Urban Dental Expenditures¹

SELMA MUSHKIN and BEATRICE CROWTHER

Out-of-pocket dental expenditures of the urban population amounted to about \$10 per person in 1950. They accounted for about 15 cents of each \$1 of total out-of-pocket medical care expenditures. The average urban family spends about \$30 a year for dental care as compared with \$197 for all medical and health services.

Dental expenditures are highly concentrated. Almost half of the more than \$900 million spent on dental care by urban families in 1950 represents the spending of less than 5 percent of the city population. About 48 percent of urban families reported no dental outlays.

Dental expenses take a larger share of the medical care dollar at ages 6-18 years than at other ages. About 28 percent of all medical spending for children of these ages goes for dental care. In contrast, only 7 percent of the medical care expenditures of those 65 years or over goes for dentistry. Dental bills of \$100 or more, however, take a larger share of the dental dollar of the middle and older age groups.

DATA COLLECTED from families surveyed by the Bureau of Labor Statistics in its 1950 study of spending habits among city families provide a basis for analyzing some aspects of the dental expenditure patterns in urban areas, where dental resources and facilities are relatively more ample than they are in rural places (1). They provide information on the concentration of dental expenses, which other surveys have by and large neglected, but which may throw some light on the financial problem of prepayment of dental services.

The design and coverage of the Bureau of Labor Statistics survey were outlined in an earlier article (2). In summary, the Bureau of

Labor Statistics interviewers obtained complete and useful information on family income and spending habits for 12,489 families, including single-person consumer units.

As a basis for a study of medical care spending variations by age groups, the Public Health Service drew a random subsample of the Bureau of Labor Statistics schedules and tabulated the information reported by the families on expenditures of individual family members. In selecting the subsample the interview schedules were stratified by the amount of total medical care expenditures. The subsample included all schedules reporting expenditures of \$1,000 or more, 50 percent of those reporting \$400 to \$1,000, 20 percent of those reporting \$200 to \$400, and 10 percent of those reporting some medical care expenditures but in amounts less than \$200. To provide a basis for evaluating medical care received by public beneficiaries, such as public assistance recipients, 50 percent of the schedules reporting no medical care expenditures were also included in the subsample. A total of 2,414 consumer units composed of about 7,639 persons were included in the subsample.

Data on family expenditures are based on tabulations of 12,489 consumer units interviewed by the Bureau of Labor Statistics. Data on individual expenditures are based on the subsample of 2,414 consumer units.

Dental expenses reported in the survey represent out-of-pocket charges incurred by members of the family for the broad range of

Miss Mushkin, an economist, and Miss Crowther, a research analyst, are with the Division of Public Health Methods, Public Health Service.

dental services, including dentures and dental X-rays. Drugs purchased on the prescription of a dentist are excluded from dental expenses.

Family Dental Expenses

Urban families in 1950 spent an average of about \$30 for dental care; excluding families who made no expenditure, the average was about \$58 (table 1). Converting the \$30 family average to a nationwide estimate of urban family dental spending yields a figure of some \$945 million, a figure which is high when compared with national income account estimates of personal consumption for dental care. This divergence between family survey estimates of aggregate dental care expenditures and the national income estimates of the Department of Commerce derived from income surveys of practitioners has been noted by others (3-5). Additional study is required to analyze these differences and determine the origin of the divergencies and the conceptual and reporting problems involved.

The data on urban family expenditures underscore the special characteristics of dental spending which mark it as different from other medical outlays. For one thing, a large proportion of consumers do not purchase dental care in a given year. In 1950 about 48 percent

of the urban families reported no expenses for dental care. In contrast, only 7 percent of the families reported no spending for direct health services, that is, spending for medical care exclusive of health insurance premiums (table 2).

Dental care spending by income groups varies more sharply than other medical care costs. Average family dental expenditures of the \$1,000 to \$2,000 income group, for example, are about one-tenth of the average dental expenditures of families with incomes of \$10,000

and over. Average expenditures for direct medical care of the \$1,000 to \$2,000 income group are about one-fifth of the average expenditures of families with incomes of at least \$10,000. This difference is attributable largely to the variation in the proportion of families in different income groups who use paid dental services. Almost 3 times as great a proportion of families with an income of \$10,000 or more report dental expenses as do families with an income of \$1,000 to \$2,000. There is little difference between the high and lower income groups in the proportion of families reporting some direct medical expenditures.

The average spent for all direct medical expenditures (that is, excluding insurance premiums) by families reporting some expenses is 4.2 times as high for families with an income of \$10,000 or more as for families with an income of \$1,000 to \$2,000. In contrast, average dental expense of the \$10,000 and over income family reporting some dental expenditures is only 3.3 times that of the \$1,000 to \$2,000 income family.

Within these averages there is considerable variation depending on the age of family members and family size, as well as other characteristics.

Age Differentials

The pattern of age differentials in dental spending for urban residents is similar to that obtained by the Health Information Foundation in its 1952-53 survey of both rural and urban families (6). Dental charges in the Health Information Foundation study averaged \$10 per person, with a high of \$14 per person 35-54 years of age and lows of \$4 per person 65 years of age or older and \$1 per person under 6 years of age. In the Public Health Service study, limited to urban residents, the high is \$13 for those 19-44 years of age, and the low is \$2 for children under 6 (table 3). The average expenditure for urban persons 65 and over in the Public Health Service study is \$6, compared with the Health Information Foundation average of \$4 in both urban and rural areas. (The percentage distributions by age group of the Public Health Service sample, of the urban population, and of dental expenditures are given in table 4.)

Table 3. Average out-of-pocket expenditures per person for dental care and for all medical care, by age group, urban population, 1950

¹ Including health insurance premiums and dental expenditures.

² Averages adjusted to Bureau of Labor Statistics aggregate medical care expenditures per consumer unit and 91-city distribution of expenditures by class.

While dental expenses account for 15 percent of total medical care expenditures of all urban residents, they account for 28.5 percent of the total medical spending for those 6-18 years of age (fig. 1). Dental expenses account for about 7 percent of total medical spending of persons 65 and over and for only 3 percent of expenditures of those 75 and over.

These averages reflect the appreciable proportion of persons in each age group who had no dental expenses during the year. Almost 70 percent of urban residents of all ages incurred no dental expenses. Excluding children under

6 years because dental services are usually not initiated until the child reaches 3 or 4 years of age (7), the proportion of persons reporting no dental expenses increases from 60 percent for those 6 through 44 years of age to 87 percent at ages 65 years and over (table 5).

Concentration in Expenses

Not only is the proportion of families purchasing dental services substantially higher in the upper income groups but a large part of all dental expenditures is accounted for by the

spending of a small part of the population. For all age groups combined almost half of the dental expenditures are made by individuals spending \$50 or more a year for dental care. The concentration of expenses differs considerably by age: In the 6-18 age group only 30 percent of dental expenses are in amounts of \$50 or more, and in the 45-64 age group almost two-thirds of the expenses are above \$50 per year (table 6).

Although a smaller proportion of the urban population in the upper age groups incurred dental charges, a large part of their dental bills

NOTE: Figures are shown in parentheses when the product of the percentages and the unweighted count of persons in the sample in the given age group is less than 10.

Figure 2. Percentage distribution of dental expenditures by size of expenditure and age group, 1950.

was made up of annual bills of \$100 or more or even \$200 or more (fig. 2). About 1 percent of children 6-18 years of age incurred dental charges of \$100 or more, and the charges in these amounts accounted for 16 percent of the total dental spending for this age group. By way of comparison, about 4 percent of persons 45-64 years of age incurred annual dental charges of \$100 or more, but their bills represented more than \$1 out of each \$2 of the total dental spending of urban residents of those ages. Their charges of \$200 or more represent

more than \$1 out of each \$5 spent by those 45-64 years of age.

Differences in spending patterns reflect in part differences in the nature of dental care needs associated with age. The large dental bills are of lesser importance in dental spending for children under 19 years of age than in dental spending of the middle or upper ages. More than 90 percent of the dental expenses for children under 6 years and about 70 percent of the dental expenses for children 6-18 years are in amounts less than \$50; only 10 percent of the

charges for those 6-18 are in amounts of \$200 or more. Preventive dentistry at preschool ages may help to reduce that part of these expenses attributable to dental neglect.

Trends in Spending

Estimates of dental expenditures published each year by the Office of Business Economics of the Department of Commerce indicate that the share of total medical care spending represented by dental expense has decreased (8, 9). In 1929 dental expenses represented 16 percent of personal medical care expenditures; in 1950, 10 percent; and in 1956 (the latest year for which data are currently available), about 9 percent. Household survey data similarly indicate some but not as marked a decline in the share of medical spending going for dental services. This decline is attributable in part at least to the reduced dentist-population ratio.

In the survey data of the Committee on the Costs of Medical Care for 1928-31, dental care represented about 18 percent of total private medical spending. The Health Information Foundation survey indicates that about 16 percent of gross medical charges went for dental services in 1952-53. The Bureau of Labor Statistics data indicate that 15 percent of out-of-pocket medical expenses of urban consumers went for dentistry in 1950.

Dental spending per person increased during the 20-year period from \$6.41 for cities of 5,000 and over population in 1928-31 (10a) to \$10 for urban areas in 1950. However, medical expenses per person increased more. In 1928-31 the city average per person was \$30.90 (10b); in 1950 the city resident average was almost \$65. (These figures are in current dollars for the year in which they were reported.)

It is not surprising in view of the increased complexity of medical care, the number of new types of professional and paramedical skills comprising the "medical care package," and the spread of prepayment coverage that dental expenditures have declined somewhat in relation to total medical spending.

Utilization of dental services has increased somewhat. In 1928-31, 74.4 percent of persons in cities of 100,000 or more population and 78.5 percent of persons in cities with populations of

5,000 to 100,000 incurred no expenses for dental care (10c). In 1950, 69 percent of urban residents reported no dental expenses. This is remarkably little improvement in utilization when account is taken of the typical pattern of dental spending in relation to income and the rise in average family income since the survey of the Committee on the Costs of Medical Care. (Factors other than income—education and social status, in particular—influence utilization of dental services, but this study provided information only on the relation to income.) Typically, dental spending, both in the percentage of persons incurring dental expenses and the average amount of expenses, rises with family income. Why has the rise in income levels and improved distribution of income among families not been reflected in a more substantial improvement in use of dental services? Similarly, why has the increased urbanization of the population not resulted in substantially increased dental care? Part of the problem may lie in the lack of comparability of the survey data and in the inadequacies of family reporting in the medical expenditure surveys. In part it may be attributed to the decline in the ratio of dentists to population.

The National Health Survey now under way will provide data for evaluating utilization of dental services among the general population in both rural and urban areas. This survey, moreover, will provide data on the types of dental services used by different groups in the population.

Child Care Problems of Physically Handicapped Mothers

16-mm. film, color, sound, 30 minutes, 1957.

Audience: Professional personnel and lay people interested in problems of the handicapped mother.

The film, made in 8 different homes, shows the problems of 1 normal mother, 3 wheelchair mothers, 1 amputee mother, 1 mother with muscular weakness, 1 using a crutch, and 1 with a leg brace. It points up the need for expanding programs to include more of the 10 million handicapped homemakers in the United States.

It was produced by the School of Economics, University of Connecticut, in cooperation with the Connecticut Team Approach Committee on Research Demonstrations and Workshops Concerning Physically Handicapped Women, and the Office of Rehabilitation, Department of Health, Education, and Welfare.

Address inquiries on borrowing and purchase to Audio Visual Center, University of Connecticut, Storrs, Conn.

"Anyone for Nursing?"

16-mm. filmograph, color, sound, 17 minutes, 1957.

Audience: Schools of nursing, nursing organizations, and high school career guidance groups.

This filmograph covers in detail nursing activities and opportunities in Public Health Service hospitals, in the Indian and international health programs, in research nursing at the National Institutes of Health, and public health nursing programs generally.

The story is presented in a light, gay manner throughout, with an occasional cartoon and simple animation.

This film is available on short-term LOAN from the Recruitment Branch of the Division of Personnel, Public Health Service, Washington 25,

Microsporum gypseum macroconidia.

The clinical features of *Microsporum* and *Trichophyton* ringworm in animals are described, followed by demonstrations of methods for examining the animals with the Wood's light and for collecting specimens for laboratory study.

The laboratory methods consist of examining the clinical materials, inoculating culture media, and in case of *Microsporum* identification of

Dental Services for Special Groups

CONFERENCE REPORT

DENTAL CARE services for the indigent, the mentally retarded, public assistance recipients, and other population groups were discussed by dental directors attending the Biennial Conference of State and Territorial Dental Directors with the Public Health Service and the Children's Bureau held in Washington, D. C., June 19-21, 1957.

Dental directors attending the conference were welcomed by Katherine B. Oettinger, chief of the Children's Bureau, and Dr. Leroy E. Burney, Surgeon General of the Public Health Service. In a following address Dr. John W. Knutson, chief dental officer of the Service, urged increased emphasis on the promotion of fluoridation. He also pointed out that the changing trend in public health from infectious diseases to long-term illnesses will require close cooperation of the medical and dental professions to achieve new public health goals.

One of the sessions of the conference was devoted to a series of table clinics on dental statistics, dental hygiene, traineeships, Hill-Burton dental facilities, fluoridation and defluoridation, group payment plans, public assistance, and research grants. Summaries of the other discussions follow.

Local Dental Clinics

Local dentists provide the technical skills and local health officers set the policies for local health clinics in Georgia, according to Dr. John E. Chrietzberg, director of dental health service, Georgia Department of Public Health. In

addition, consultants from local, regional, and State health departments take part in organizing and operating the clinics.

One of the first steps taken by the department of health in developing a clinic is to ask the community to set up an advisory committee. This committee is made up of several dentists, school people, representatives from the welfare department, public health personnel, and representatives from the PTA, service clubs, and other groups with specific interests in a service program.

Chrietzberg said that the committee is asked to establish a means test, which is not done at the State level. The State health department generally advises the committee and provides it with the methods that are being used in other communities. Committee members help raise local funds for transporting youngsters and maintaining the clinic. They also help to buy supplies. "All this makes the community feel it is their clinic," he said, "and consequently, the clinics are effective and most likely permanent."

Of the 45,932 children admitted to the 116 clinics in Georgia, 16,000 received complete treatment; 29,932 received only partial treatment, but many of these received total treatment of permanent teeth. The total cost of the program was \$69,745.

Payments by the clinic are modest, the dentist receiving \$5 and the assistant \$1 an hour. In Chrietzberg's opinion, the experience might well prove helpful some day in planning prepayment dental plans on a maintenance pro-

gram. The clinical program has also encouraged many dentists to do more dental work for children.

Indigent Care in Maryland

Private dental office treatment for indigents provided by the Maryland medical care program was described by Dr. Edward Davens, deputy director of public health, Maryland State Health Department. Presumably programs of this kind can be developed in nearly all States, he said, citing the amendment of the Social Security Act of last year which will provide medical and dental funds to States for four categories of public assistance: old-age assistance, aid to the permanently and totally disabled, aid to dependent children, and aid to the blind. In most States the funds will be administered by welfare departments.

In the cleft-palate program, the clinic approach is integrated because the problem is not limited to cosmetic or plastic surgery, but involves communication and dental as well as medical and audiological problems. The program is operated jointly by the State health department, the Johns Hopkins University School of Medicine, and the University of Maryland Dental School.

Davens concluded with the hope that there would be a continuing emphasis on the fluoridation of public water supplies in Maryland. "Today," he said, "85 percent of our people who use central water supplies drink fluoridated water."

The Mentally Retarded

In Pennsylvania, if an agency bears the cost of providing dental treatment to mentally retarded and cerebral palsied children who are indigent or if the dentist gives free treatment to such patients, the State health department will pay for hospitalization of patients requiring general anesthesia or special techniques applicable only in a hospital. According to Dr. Linwood G. Grace, director, division of dental health, Pennsylvania Department of Health, who described the program, very few dentists would accept mentally retarded and cerebral palsied children at the outset. There was a great need to improve the dentist's knowledge of the necessary technique.

With the cooperation of the University of Pennsylvania in Philadelphia and the University of Pittsburgh, three training courses were conducted to teach practicing dentists the required special techniques. The courses were highly successful, he said, and will probably be repeated as the program grows.

Children's Bureau Program

The \$1 million earmarked by Congress for special projects and services for mentally retarded children in fiscal year 1957-58 is being used by the Children's Bureau for demonstrations or pilot programs in 24 States, reported Dr. Arthur J. Lesser, director, Division of Health Services, Children's Bureau. These programs, while providing clinical services, emphasize treatment of the more severely retarded and younger children. The medical or clinical components are basic, but a team approach integrates the services of a physician, social worker, and psychologist.

"Only 10 percent of retarded children are in institutions," Lesser said. "Most parents want to keep their children at home, but they need help if they are going to do a good job."

In 1955, some 278,000 children received services from physicians under this program. About half of these children have an orthopedic handicap, and the rest have various conditions such as heart disease, cleft palate, epilepsy, and cerebral palsy. The increase in the numbers of children in this program since about 1940 has been largely in the nonorthopedic groups.

Lesser explained that treatment of the crippled child has moved away from the almost exclusively orthopedic and plastic surgery programs to one which is becoming a pediatric program for children with long-term illnesses or physically handicapped conditions.

A considerable amount of program funds goes into training of all sorts: dentistry, maternity care, public health, audiology, and so on.

Public Assistance Programs

Discussing dental care for public assistance recipients, Dr. Thomas B. McKneely, medical consultant, Bureau of Public Assistance, Social Security Administration, outlined the four categories of "needy" persons covered by Fed-

eral aid to States: persons 65 years of age and older; persons who are blind; dependent children; and persons who are permanently and totally disabled.

These four groups in January 1957 included more than 5 million individuals who received assistance amounting to over \$227 million.

The primary purpose of public assistance, he said, is to help needy people secure the basic necessities for living, such as food, shelter, clothing, and other items. The Bureau of Public Assistance has long recognized medical care as one of the basic necessities, and Federal matching funds within the maximum have been available to the States.

Before 1950, matching money was available only for unrestricted payments to the recipients. Amendments to the law in 1950 permitted Federal sharing in payments made directly to vendors of medical services. The 1956 amendments established a separate matching formula for medical expenditures. This formula makes available to States a monthly amount not in excess of one-half of \$6 times the adult recipients in each category and \$3 times each child included in the aid to dependent children category. Money under this formula is granted to States on the basis of the amount expended each month. Each category is a separate program with separate fiscal accounting. Thus, funds expended in one are not transferable to another category.

Dental care comes within the broad definition of medical care. A 1946 study of medical care in public assistance showed that out of each dollar spent, dental care accounted for 3 cents in the old-age assistance category; 12 cents for aid to dependent children; and 9 cents for aid to the blind. The proportion of the caseload receiving dental care during the 1946 study period by category was, respectively, 1.4 percent, 4.8 percent, 2.5 percent. There was no program for aid to the permanently and totally disabled. Although the figures are old, McKneely said, they do show there was some dental care in the program and that there was recognition of the greater need among children for dental care.

The Bureau of Public Assistance, he continued, does not require a State to include medical care in its plan. It is a State option to pro-

vide none, little, or much medical care. Because there is little expensive long-term medical care in the aid to dependent children caseload it is expected that more funds will be available for dental care. States are being urged to give consideration to expanding dental care for children. Professional guidance in this area is needed, McKneely feels.

Vocational Rehabilitees

The goal of the State program of the Office of Vocational Rehabilitation is restoration of physically handicapped adults to gainful employment through provision of appropriate medical, dental, social, and educational services, stated Dr. Samuel S. Herman, acting medical director, Office of Vocational Rehabilitation. Although data are scanty, there is evidence that participation by dentists in this program has been little more than minimal, despite the substantial growth during recent years in State, Federal, and private funds for vocational rehabilitation.

Well-defined circumstances under which dental defects may be considered vocationally handicapping are the disabilities of persons with cleft palates or of those who have had extensive facial surgery for removal of a malignancy. In these instances, Herman said, unintelligible speech, cosmetic deformity, and inability to eat may be substantial employment handicaps. In such cases, the dentist is called upon to provide services ranging from operating procedures to providing complex prostheses and appliances.

In other instances, the defects may not of themselves represent a substantial employment handicap, but may directly contribute to the severity of another condition which hinders employment. He gave as an example severe peripheral facial paralysis traceable, in the opinion of the examining neurologist and dentist, to a dental focus of infection.

A more frequent need for dental services in the vocational rehabilitation program arises in connection with an employment handicap stemming from multiple disabilities. If a combination of disabilities makes it impossible for the individual to work, it may be necessary to provide corrective measures, including compre-

hensive dental care, to bring about a state of health conducive to satisfactory functioning on the job.

State agencies are encouraged by the Federal office not to establish arbitrary limitations on the types of dental services provided, nor on the amount of money expended for this purpose.

The Office of Vocational Rehabilitation, Herman concluded, also encourages a free choice of dentists and change of dentist either at the request of the client or the dentist.

Care for Handicapped Children

Children with such conditions as cerebral palsy, mental retardation, and muscular dystrophy suffer from the dental neglect and poor care that prevails in many parts of the world, according to Dr. Manuel M. Album, research associate in oral pathology, University of Pennsylvania School of Dentistry. He maintained that recognizing the existence of such dental conditions in these children and the fact that poor dental health is closely related to the overall physical health of the child should be a prime concern of the dental profession. "Dentists have been somewhat reluctant and indifferent in their treatment of these children. The fear of inflicting injury to themselves, as well as to their patients, is caused by their lack of information on the medical backgrounds of the children."

The necessities of everyday living is an important part of the child's motivation and integration into normal life. The desire and willingness of these children to learn and the competitiveness they exhibit makes one realize the deep feeling they have for recognition.

They should receive the same dental care as our own children, Album said. Primary teeth should not be injudiciously extracted, but should be allowed to follow normal growth patterns. Badly decayed teeth, loss of teeth, and severe cases of malocclusion restrict the progress of speech in these children.

According to Album, there is no such thing as an untreatable child, no matter how severe his physical or mental condition might be. With today's modern methods one can insure good, thorough dental treatment. Because of

the child's condition, it may become necessary to adjust the approach and treatment to the individual patient. Cavity preparation and filling should generally correspond to the normal, daily routine.

Clinical procedures should be attempted in the dental office without the use of medication, he said, since this procedure enables the dentist to become better acquainted with the child and his condition. Local anesthesia can be given for cavity preparation as well as for single extractions. If it becomes impossible to work under normal means, the patient can be given one of the muscle relaxing agents or premedication. If all of these measures fail, then the child should be admitted to the hospital.

After the child has received a thorough physical examination and been found suitable for general anesthesia, all of the dental work can be done at one time and the mouth completely rehabilitated. Following this technique, personalities often improve rapidly and children who were difficult to work with in the dental office become excellent patients. The technique enables the dentist to establish a starting point for future dental needs. Album warned against the dentist's use of this method as a crutch or tool to slough off his obligations to the child. It should only be used as a last resort when other procedures fail, he said.

"Children with a handicap must be respected as individuals, so that they can attain their rightful place in society, he concluded."

The Dental Profession

Dr. J. H. Eshleman, chairman of the American Dental Association's Council on Dental Health, reviewed the guiding principles set by the association to aid its agencies in developing dental care programs operated under the auspices of the Federal Government and to assist constituent societies in developing special programs giving dental care to specific groups.

In these programs, the dental profession has established dentistry as a basic health service in the health programs of the Nation and has attempted to integrate dental care into general health care. The development of health pro-

grams for persons with mental and chronic illnesses and the expansion of hospital facilities for the care of such patients are accompanied by a growing recognition of the need for complete dental departments in all types of hospitals. Chronic illness programs, added Eshleman, must provide for the homebound patient who does not require hospitalization but who does require dental care.

He noted that emphasis in health programming has shifted from the individual to the group. Consequently, the profession's expanding knowledge and skill in the management of dental disease must be adapted to the socioeconomic environment of patients, the study of which demands the aid of other sciences such as sociology. Furthermore, the future of dental practice depends on fuller use of the specialized resources of business administration, production technology, and production efficiency.

Eshelman pointed out that there is a trend toward the development of many different forms of group dental practice. Efforts are being directed toward the goal of eliminating the heavy burden of costs for dental health services. An essential and accompanying effort must be made to strengthen the capacities of the State and local dental societies and dental components of health departments.

Dental Resource Studies

"Effective resource studies are not limited to counting heads and viewing with alarm the shortages in personnel which the count reveals," said Dr. Walter J. Pelton, chief of the Division of Dental Resources, Public Health Service. These studies, he asserted, must explore any areas of activity directly or indirectly affecting dentistry's efforts to protect and improve America's oral health. The Division of Dental Resources makes a continuing effort to do this, as indicated by its activities in the last fiscal year.

Pelton cited the division's study in 1956 of requirements through 1975 for dentists and dental hygienists in 11 western States, Alaska, and Hawaii. Prepared for the Western Interstate Commission for Higher Education, the booklet entitled "Dental Manpower Requirements in the West," was published by the commission

in July 1956. A similar study of 16 southern States was conducted in cooperation with the Southern Regional Education Board, which is planning its publication. These studies and two others now in the initial stage—one covering New England and the other, all 48 States—will provide a working base for long-range planning needed to offset the decline in dentist supply.

In education, said Pelton, the division completed a survey of characteristics, finances, and practice plans of dental and dental hygiene students in cooperation with the Council on Dental Education of the American Dental Association. Originally published in the association's journal, it has been reissued as a pamphlet entitled "How Students Finance Their Dental Education." Two additional articles, "The Hygienist as a Student" in the *Journal of the American Dental Hygienists' Association*, October 1956, and "Costs and Income Sources for Dental Students" in *Public Health Reports*, May 1957, are based on the survey, and another, containing added information on loans and scholarships, is in preparation.

Pelton then described two major research programs in educational methods which were also begun in 1956. The first is a pilot project to determine the best techniques for training dental students to work with chairside aides. Although it is only in its first year, 3 of the 5 schools signing cooperative agreements have started active training projects. Probably more schools can be expected to participate in the future. The second program, a study of dental assistants and their jobs, will augment a joint project of the American Dental Assistants' Association and the American Dental Association concerned with training courses for assistants and accreditation standards. Both of these programs are designed to aid development of better curriculums and training methods and to promote more efficient use of professional skills, integral parts of resource planning.

One of the Public Health Service series of manpower surveys, entitled "Health Manpower Source Book, Section 8: Dental Hygienists," has been completed by the division. Pelton feels that it is probably the most complete

analysis of current professional status, availability, and future need for dental hygienists.

Prepaid dental care, expected to have a great impact on dental demand, is a long-term research program. Two conferences were held, the first with prepayment executives, health economists, and dental leaders, and the other with health insurance company representatives; others are in the planning stage. A report entitled "Predictability of Dental Care Needs of Adults" was published in the *Journal of the American Dental Association*, June 1956, and two others, "Dental Experience of the St. Louis Labor Health Institute" and "Utilization Patterns of Free Clinic Facilities by Two Population Groups," are in progress. These studies, analyzing various types of utilization, chair-time, and need patterns in group clinics, should provide important facts in an area for which available data are limited and unsatisfactory, said Pelton.

Also in preparation is a catalog of all existing prepayment plans with details of organization, eligibility rules, coverages, and rates.

He then listed the projects which may be included in the division's future research in prepayment plans:

- An extension of the study of utilization patterns in the Group Health Association dental clinic, Washington, D. C. Supplementing a 1954 report entitled "Comprehensive Dental Care in a Group Practice," it will emphasize long-term service demand patterns.

- The organization and operation of State dental service corporations to study ways by which such a corporation serves as intermediary between dentists and groups seeking dental care.

- The organization, operation, and implications of postpayment dental plans.

"Because of the nature of its research," Pelton said, "the Division of Dental Resources needs and has always received the interest and cooperation of leaders in many fields. That this interest has not died with the publication of our studies but is instead being translated into intelligent and forward-looking action, is, after all, the real achievement of the year's work."

Fluoride Effects on Tooth Surfaces

A study comparing benefits to individual permanent teeth when fluoride ingestion starts at birth and at various ages was described by Grace C. Scholz, statistician, Division of Dental Public Health, Public Health Service. Her report was preliminary to preparation of the full results of the study for publication, she said.

The study, made during 1944-55, was based on the results of 71,000 dental examinations of children aged 5-16 with continuous residence in Grand Rapids and Muskegon, Mich., and Aurora, Ill. These children were grouped on the basis of their homogeneity with respect to age and the length of time they had been drinking fluoridated water. Data for each tooth space of each group were tabulated, and standard statistical measures were used for comparing groups.

Fluoridation

Cities treating their water with alum can now cut the cost of fluoridation at least two-thirds by using fluorspar instead of some other fluoride compounds, according to Franz J. Maier, chief of the Engineering and Chemistry Laboratory, Division of Dental Public Health, Public Health Service.

Heretofore, fluorspar, the least costly of all fluoride compounds, could not be used for fluoridating water supplies, said Maier. It does not dissolve readily. This difficulty was overcome by the development of a fluorspar dissolver. In feeding the fluorspar, an alum solution dissolves the compound, which is fed into the water by a solution feeder.

Nonfluoride Hypoplasias

The great majority of enamel hypoplasias commonly seen is not due to fluoride ingestion, reported Dr. Albert L. Russell, chief, Epidemiology and Biometry Branch, National Institute of Dental Research, Public Health Service. Therefore, he maintained, care should be taken in excluding such cases when computing the community fluorosis index. Incorrect diagnosis of nonfluoride enamel hypoplasias as fluoride-caused has caused confusion, among serious workers in this field, as to the meaning and severity of fluorosis. It has provided plau-

sible if spurious arguments against fluoridation of community water supplies.

Reports of the prevalence of nonfluoride enamel opacities differ and some of the differences may be real, Russell said. Hurme reported one or more opacities in 83 percent of the children in a new England community; Zimmerman saw 36 percent in a Maryland group; Syrrist found "white spots" in 19 percent of a Norwegian group; Parfitt reported a 50 percent prevalence in London children; and Forrest, a 70 percent prevalence in children of Essex and Surrey; both Davies and Russell found such opacities in about 20 percent of the children in Kingston, N. Y. Not one of these groups used a domestic water with more than 0.2 p.p.m. F,

so that none of these opacities could have been due to fluoride ingestion.

Both Davies and Forrest, Russell continued, make the point that these common nonfluoride opacities are much more disfiguring than the slight fleckings seen in communities with about 1.0 p.p.m. F. In children of Essex and Surrey, Forrest found blemishes so severe that they would have been classified as moderate, had they been due to fluoride, in 17 of 259 cases.

In this situation the obligation of the dental public health worker is plain: to learn to diagnose these conditions in the field and to determine their prefluoridation prevalence and character in order to avoid their being ascribed, post hoc, to change in the water supply.

Retirement Histories Studied

The Social Security Administration is asking 3,000 newly retired persons throughout the country to report over the next 12 years how they get along in retirement.

Information obtained through a series of interviews with the older persons will be part of a long-range study to provide more information about the circumstances and problems encountered by social security beneficiaries in their later years.

After the initial interviews in 1958, followup visits in the homes of the same people will be made at intervals of 1 or 2 years over a 12-year period to find out how their situation changes during retirement and the adjustments they make. The retirement experience of this group is expected to throw new light on the problems, interests, and capacities of older people generally.

The initial interviews, which will be conducted for the Social Security Administration by the Bureau of the Census, will cover the year before the interviewees apply for social security benefits so that the retirement histories can be developed from the beginning.

The study will seek the following information from the 3,000 persons:

- How many have sufficient income from their own resources, including old-age and survivors insurance.

- What they do if their financial resources become inadequate to meet their needs.

- How their chief items of expense change as they get older.

- What they do if they incur catastrophic medical costs.

- How long those who were financially independent at the start of their retirement remained so and under what circumstances they get support from their children, public assistance, or some other source.

- Their attitudes toward their retirement and its problems.

- What they think are their greatest unmet needs and how these affect their adjustment to old age and retirement.

A panel of experienced consultants conferred with the research staff of the Bureau of Old-Age and Survivors Insurance in working out the questionnaire and advised on technical problems. The consultants were Dr. Gordon Streib, professor of sociology, Cornell University; Dr. Ethel Shannas, National Opinion Research Center, University of Chicago; Miss Anne Geddes, Community Research Associates, Inc.; Dr. Nancy Bayley and Dr. Olive Westbrooke Quinn, National Institute of Mental Health, Public Health Service; and Dr. Oswald K. Sagen, Public Health Service.

Forecast of Dental Service Needs in the South

WALTER J. PELTON, D.D.S., M.S.P.H., and RUTH DEE BOTHWELL, B.A.

TO ERASE the difference between the ideal and the merely adequate in dental care is one of the greatest challenges in public health today. But since the ideal must wait upon the practical, we are concerned with the more realistic goal of providing the dentists the South will need to meet the actual demand for dental care.

This is not easy to do. State and regional boundaries are much more clearly defined on a map than they are in public health planning. The problem which the South faces in providing for the future dental health of its citizens is neither unique nor isolated. The dental manpower problem in Arizona is not only similar to that in Alabama, but the manner in which Arizona solves it will affect Alabama's answer too. A national shortage of dentists has developed—a shortage already limiting the amount of care which people who want it can get.

This shortage dates from the early 1920's, when improved standards of dental education resulted in the closing of substandard schools, and caused a sharp cut in enrollment. During the depression of the thirties, a further reduction occurred. By the time World War II began, there were fewer dentists than there were

prior to 1930, only about half as many students were attending dental school as in the mid-twenties, and not enough new dentists were being produced to replace older dentists who had died or retired. When large numbers of dentists entered the service, the shortage was further aggravated.

Persons-per-Dentist Ratio

The years since the war have seen expansion in training capacity and a rise in new dentists entering the profession. By 1955, nearly 3,100 dentists were graduated from the Nation's schools—twice the number of the last prewar class of 1941. But the population has grown much more rapidly than has the supply of dentists. By 1955, the persons-per-dentist count had risen to 2,169 from 1,870 in 1940 and 1.728 in 1930. With our larger population of 1955, it would have taken nearly 19,000 more dentists than were then in practice to restore the 1930 ratio.

Ratios in every region of the country are less favorable than in 1930, and, for some States, less favorable than in 1920. The States most affected by this adverse trend are those with the greatest population gains. Georgia, Louisiana, South Carolina, Virginia, Delaware, Maryland, West Virginia, and Texas have continued to lose ground, with current ratios considerably less favorable than those of 1940 or 1930. In four of these States, the persons-per-dentist count is now higher than at any time in this century. In fact, the only State in the

Dr. Pelton is chief, and Miss Bothwell, public health research analyst, of the Division of Dental Resources, Public Health Service. The paper was presented in substantially the same form before the American Public Health Association, Southern Branch Meeting, at Asheville, N. C., on May 31, 1957.

South appreciably better off than it was in 1930 is Arkansas, and the only State which has succeeded in stabilizing the count at the 1930 level is Oklahoma. Both have been subject to heavy population losses due to migration. In the remaining Southern States, the 1955 persons-per-dentist counts are considerably better than the 1940 ratios, but are not at the 1930 standard.

The South as a whole, moreover, is still the least well supplied of any region, with only 1 dentist for every 3,572 southerners in mid-1955. This is almost two-thirds more than the number of persons served by the average practitioner in the United States (fig. 1). Florida, with nearly 2,500 persons per dentist, ranks first among the Southern States, but only 24th in the Nation. The remaining Southern States occupy 15 of the bottom 17 positions. At the end of the list is South Carolina with almost 6,000 persons per dentist, about 4 times the number served by the average dentist in one of the top-ranking States.

Although dentists are no more unevenly distributed in the South than in most regions of the country, maldistribution is especially serious because the overall supply of dentists is so limited. In the average metropolitan area, there is 1 dentist for every 2,200 persons. But in the smaller urban counties, there is only 1 for every 3,000 persons, and in counties with no

city of 10,000 or more population, the average dentist serves nearly 4,700 persons. In some States, persons-per-dentist ratios in these less populous counties reach an average of nearly 7,000. In Georgia, 1 in every 4 counties is without a dentist.

Actually, more ground has been lost than is indicated by trends in persons-per-dentist ratios. Because so few dentists were added in the years before the war, we now have a large concentration of dentists in the older age groups. The proportion 55 years old and over about doubled between 1930 and 1950, and the proportion reaching 65 years of age nearly tripled. By 1950, about 1 in every 3 dentists in the South was at least 55 years old, and 1 in 9 had reached 65 years of age. As a result, nearly half of the 14,000 dentists now practicing in the South must be replaced by 1975. Among the Southern States, Delaware, Florida, Louisiana, Oklahoma, and West Virginia face the most serious replacement problems.

Factors Affecting Demand

These needs still represent only a fraction of the total number of dentists required in the future. The population is growing, incomes are climbing, and other changes are taking place to make dental care more accessible in the

Figure 1. Dentist-population ratios in the United States and in the South.

Figure 2. Proportion of urban population in the United States and in the South.

future and more likely to be sought than at present. The South, even though growing less rapidly than the rest of the country, has an annual increase in population of close to 680,000 persons a year compared with an average of 360,000 in the years before the war. Thus the equivalent of a new Dallas or a new Miami emerges full grown each year. Conservative population projections show that the South can expect to see about 640,000 persons added to its present population of about 50 million each year during the next 10 years, and then, in the following 10 years, when all the postwar "babies" start having children of their own, 825,000 a year will be added. By 1975 these figures will mean 15 million new potential consumers of dental services in the Southern States.

More important than growth, however, are changes taking place in the makeup of the population. We are, for example, rapidly becoming a nation of city dwellers. And city folk find it less inconvenient to visit dentists than do their country cousins. Moreover, city folk generally have jobs demanding a minimum standard of personal appearance and have greater cash incomes to pay for dental services. The South is still much less highly urbanized

than are other regions, but it is rapidly catching up with the remainder of the country (fig. 2). In 1930, only 33 percent of all southerners lived in cities; 23 percent less than the national average. Now an estimated 49 percent are urbanites, and the difference between the South and the country as a whole is only 16 percentage points. By 1975, if the trend continues, the southern percentage will be within 9 points of the national average.

This change means that the rural population will shrink, and the 15 million new southern residents projected for 1975 will all have been added to the city population. As a result, instead of the 25 million urban residents of 1955, there will be 42 million in 1975, about 17 million more people living in towns and cities, subject to all the subtle influences that make urban residents the largest consumers of dental services. A good share—perhaps upwards of three-quarters of the net increase in the population during this period—will be registered by the big metropolitan areas, thus facilitating access to specialists' as well as generalists' services.

Education for the average southerner will also be greatly increased (fig. 3). We may assume that the percentage of southerners completing high school will rise until by 1975 it

reaches the level that in 1950 characterized the country as a whole. Approximately 28 percent of all southern adults between 25 and 65 years of age in 1950 had completed high school. But less than a fifth of those 45 years old or over had done so. These will be replaced by better educated youth. And, of course, the number of people reaching 25 years of age during the next 20 years will be very much larger than the number leaving this age group, so that 4 in every 5 people added to the adult population between 1950 and 1975 will have finished high school. Consequently, by 1975, the proportion of high school graduates within the total group will have advanced to 46 percent from only 28 percent in 1950. Probably an even greater proportional change will occur in those receiving college training.

This rise in education in the South will have far-reaching consequences: Adults in general and, more important, the parents among them are likely to have greater appreciation of the value of oral health than is the case today.

Significantly, the States most affected by new levels of education will be those in which these levels now lag most seriously: Mississippi, the Carolinas, Georgia, and Alabama. In States now at the top of the education scale, the number of high school graduates among the adult population will probably double by 1975, but more than triple in the low-ranking States.

The ways in which southerners make a living are also changing in a way that spells greater future demands for dental care. The trend is toward better paying occupations. Professional and technical workers, proprietors and managers of nonfarm businesses, and clerical and sales workers—the so-called white-collar groups—accounted for more than two-thirds of all employment expansion between 1940 and 1950, although they made up only one-fourth of the total work force in 1940. The number of clerical workers increased by about 80 percent, and the professional and managerial groups and the sales group by nearly 50 percent.

Skilled craftsmen showed the second largest

Figure 3. Current and expected portions of adult population with at least high school education, in each of the Southern States.

Figure 4. Average income in Southern States as percentage of United States average, for 1940, 1955, and 1975 (projected).

gain of all, increasing by more than 70 percent. The semiskilled occupations, on the other hand, registered a 50 percent increase, while the unskilled group gained but 11 percent. The farming occupations declined.

To a great extent these changes reflect a nationwide pattern. In the South they were far more pronounced during the 1940's than in the country as a whole. They mirror the gradual transformation of the region's economic character.

Southern industrial growth, both during and especially since the war, has been significant, although the region is still more dependent upon agriculture than are other sections of the country. The percentage of the Southern States' income from agriculture was cut in half between 1940 and 1955. At the same time, the percentage increase in southern manufacturing output (as measured by value added to raw materials by fabricating and processing) was a fifth larger than the national rate of increase for this period. Only Maryland, North Carolina, Virginia, and West Virginia failed to outpace the Nation during this period of phenomenal industrial growth.

The shifting economic base of the region has been important in improving the economic status of the average southern citizen, so that he is increasingly able to meet the costs of dental care.

A nationwide survey in 1953 by the Health Information Foundation showed that only 17 percent of the members of families with annual incomes of less than \$2,000 had any dental care within a year, compared with 57 percent of those from families with \$7,500 or more. Dental expenditures in excess of \$45 for the year were reported by less than 10 percent of the low-income families, but by 40 percent of families with higher incomes.

Per capita income in the South has risen almost steadily ever since 1930, in absolute terms and as a percentage of the national average. In the last prosperous year before the depression, per capita income was only 59 percent of the national figure. By 1940, it had climbed to 64 percent and by 1955 to 76 percent. Projections of this trend indicate that by 1965 income in the South will be only 13 percent below the national average, and by 1975, but 4 percent.

When we apply this larger percentage for

1975 to an estimate of what income in the United States will be in 1975, the resulting change for the South is breathtaking. Parenthetically, this national figure is based on projections which already appear conservative. Expressed in 1955 dollars, average personal income in the Nation will rise from about \$1,850 now to about \$2,550 in 1975, an increase of about \$700. Southern per capita income, however, will rise by \$1,050, climbing from \$1,400 to \$2,450.

Where incomes are already above the national average, they will tend to drop as a percentage of the national figure. In most of the States, however, incomes will rise more rapidly than in the Nation and by 1975 will be a much higher percentage of the national total than they are today. By 1975, Delaware, Oklahoma, Maryland, Texas, and Virginia will have average in-

comes exceeding the national figure. South Carolina will make the greatest progress (fig. 4).

Future Manpower Needs

With per capita income going up to nearly twice its current level and the population growing by some 15 million, the total income available in the Southern States will increase enormously by 1975. If we assume that these States will spend no greater share of that future income on dentists' services than they do today, the South will need approximately 16,000 additional dentists by 1975.

Yet today the South has fewer dentists in relation to income than any other region, even after full allowance is made for low educational attainment and the large rural population. For

Figure 5. Current and projected need for dental services in the South.

this reason, it is realistic to assume that future demand will at least equal that of 1955 in the average State and will more probably approximate the average for the 24 top-ranking States, provided again that differences in education and urbanization are taken into account.

To increase the dentist supply in each Southern State sufficiently to meet the demand level existing in today's average State, nearly 23,000 additional dentists will be required by 1975.

However, to bring the dentist supply up to a level equivalent to the average among the 24 top-ranking States today, a level adequate for meeting probable demands for service, about 29,000 more dentists will be needed by 1975. Add to these figures the 7,000 necessary as replacements for those who die or retire and the results are staggering.

At every level of estimate, Texas, Florida, Virginia, and Maryland account for approximately half of the region's entire requirements. Delaware and South Carolina will have greater proportionate needs, however. In these States, additions and replacements needed by 1975 to meet probable service demands are equal to about four times their current dentist totals. Even Arkansas, Mississippi, Oklahoma, and West Virginia, with the smallest proportionate

needs, will have to attract $1\frac{1}{2}$ times as many dentists by 1975 as they have now.

Estimates of future supply prepared 2 years ago by the Division of Dental Resources, Public Health Service, indicate that the Southern States will fall seriously short of these goals. In spite of current and projected expansion in training capacity, it seems unlikely that the region can build up its dentist supply sufficiently even to maintain the status quo unless training facilities are substantially increased.

What the South can do to avert the acute shortage of manpower is now under study by the Southern Regional Education Board, set up and supported cooperatively by the Southern States to further education opportunities of their youth.

The manpower requirements presented here are really minimum requirements for attaining a standard of oral health that we already know to be far from satisfactory. Staggering as they may seem from a distance of 20 years, the estimates of future needs are only a fraction of the dental force necessary to provide the southern people with the care that they should have. As realists, we accept the lesser goal of meeting demands for dental care, but we must intensify our efforts to stimulate people to seek the care they need. In dentistry as in all health care, nothing less than the ideal can ever be adequate.

Course in Epidemiology for Nurses

Epidemiological principles, the role of the laboratory in epidemiology, and the application of practical statistical methods to the problems in field epidemiology will be studied in terms of current major communicable diseases from April 14 through May 2, 1958, at the Communicable Disease Center in Atlanta, Ga.

Those eligible for admission to the course are communicable disease nursing consultants, public health nursing supervisors, educational directors, qualified public health staff nurses, industrial nurses, instructors in schools of nursing, and other nurses having supervisory, teaching, or consultant functions.

Application forms and further information can be obtained from the Chief, Nursing Section, Epidemiology Branch, Communicable Disease Center, Public Health Service, 50 Seventh Street NE., Atlanta, Ga., or from the director of public health nursing of the State health departments. The closing date for acceptance of applications is March 17, 1958.

World Incidence Of Anthrax in Man

HAROLD N. GLASSMAN, Ph.D.

MAN and a wide spectrum of animal hosts are susceptible to anthrax. The disease is enzootic in many areas of the world, with concomitant contamination of the soil in those areas. The disease occurs in the economically important domestic animals—sheep, cattle, horses, goats, swine—and it is largely from contacts with these animals or with industrial raw materials derived from such animals (hair, hides, bristles) that man becomes infected.

Existing reviews of the extent of anthrax in man throughout the world (1, 2) have definite limitations. The epidemiological monographs of Simmons and co-workers (1) make what are primarily qualitative references to the incidence of anthrax in a number of countries. A recent paper by Kaplan (2) which was presented at the Symposium on Anthrax in Man held at the University of Pennsylvania in 1954 reports quantitative statistical data on the incidence of this disease but restricts its attention to the years 1951–53. A better appreciation of the world distribution of anthrax in man can be obtained by consideration of epidemiological reports covering a longer period of time. This is true because a number of nations wherein anthrax has been prevalent in recent decades currently do not submit epidemiological statistics to the World Health Organization.

The incidence of human anthrax in a number of selected countries has been tabulated for the period 1924–53 (see table). The epidemiological data have been extracted from statistics published by the World Health Organization for the years 1939–53 (3), and by the Health Organization of the League of Nations for the years 1924–38 (4), and computed as average experience per year at 3-year intervals.

Dr. Glassman is assistant scientific director of the laboratories of the Army Chemical Corps at Fort Detrick, Frederick, Md.

The incidence of human anthrax is probably correlated with the enzootic status of the disease in the animal population of the country or, as in the United States, with the importation and industrial use of infected animal products. There is no necessary relationship between the population of a given country and the incidence of this disease. For example, the Cape Verde Islands, with a population of approximately 148,000, has had from 52 to 105 cases per year for the last 4 years for which statistics are available (1950–53). Other examples of comparatively small countries with a high incidence of human anthrax are Kenya with an experience of 200 to 1,000 cases per year in a population of approximately 6,000,000; and Portugal with an experience of 1,174 to 2,270 cases per year in a population of approximately 8,000,000.

Inspection of the table reveals that human anthrax is prevalent in Africa (French West Africa, Kenya, Ruanda-Urundi, Tanganyika), South America (Argentina, Chile, Uruguay, Venezuela), Europe (Bulgaria, Italy, Portugal, Rumania, Spain, Yugoslavia), the Near and Middle East (Iran, Iraq, Turkey), and Eurasia (U.S.S.R.). Only a few cases are being reported currently from North America and Oceania.

It is interesting to note that, in countries where the incidence of human anthrax is high and where statistics are available over a number of years, there is no evidence of any significant change in the incidence of anthrax over the 30-year period 1924–53.

There appear to be adequate reasons to conclude that the statistics of the international health organizations relative to the incidence in man of anthrax are understatements of the actual facts. Reasons for such a conclusion are:

1. Communicable diseases in general are under-reported. Among the factors that would be of particular importance in considering the completeness of the reporting of human anthrax would be the accuracy of diagnosis of this disease. It has also been suggested that in countries where the term "charbon" is used for both anthrax and carbuncles, inaccuracies in reporting may result.

2. This disease is prevalent in many coun-

tries which do not observe the most advanced public health practices (for example, various portions of Africa). Reports from such countries cannot be expected to represent the actual number of cases occurring.

3. Anthrax is not a notifiable disease in many countries where there are a priori reasons to believe it occurs with some frequency (for example, Afghanistan, Algeria, China, Czechoslovakia, French West Africa, and Iran).

4. A significant percentage of cases of human anthrax go unreported even in countries where public health standards are high and where notification of the disease is compulsory. For example, in the United States in fiscal year 1956, a total of 29 cases of human anthrax were reported to the National Office of Vital Statistics. The Epidemiology Branch of the Communicable Disease Center, Public Health Service, has found and obtained surveillance data on nine

Incidence of human anthrax in selected countries, 1924-53¹

additional cases which apparently were unreported (Division Project No. 201-E-45).

5. Several countries which currently do not submit epidemiological statistics for inclusion in World Health Organization reports have, in reports published some time during the past 30 years, indicated that human anthrax occurs with some frequency within their borders (see entries for Bulgaria, Hungary, Rumania, and U.S.S.R. in table). The following countries did not submit data for inclusion in the most recent (1953) yearbook on epidemiological and vital statistics of the World Health Organization: Albania, Bulgaria, China (except Taiwan), Czechoslovakia, Hungary, Liberia, Poland, Rumania, Saudi Arabia, U.S.S.R., and Yemen.

The countries presently providing their statistics on the incidence of human anthrax to the World Health Organization report a total of approximately 9,000 cases per annum. When one reviews the statistical data from the League of Nations and the World Health Organization for the period 1924-53 (see table), and gives due consideration to the reported data understating the actual situation for the reasons out-

lined above, one can reasonably conclude that the incidence of human anthrax in the world in recent years has amounted to 20,000 to 100,000 cases per annum. Anthrax is thus seen to be a much more frequently occurring disease in man than one might conclude from considering only the experience in such countries as the United States. It is also worth reiterating here that the incidence of this disease in many parts of the world appears essentially constant for the years under review.

Mental Health in Industry

Results of a survey of industrial mental health conducted by the National Institute of Mental Health, Public Health Service, at the request of the State and Territorial mental health authorities, have been compiled and issued under the title "A Review of Mental Health in Industry."

The review contains a summary of the recent literature, a bibliography of 150 titles dealing with psychiatry and mental health in industry, a description of representative mental health programs, and a list of films on human relations in industry. It also provides an overview of the medical aspects of industrial mental health.

The publication was prepared by the Institute's Community Services Branch, which furnishes technical assistance and consultation to the States in the conduct and development of their mental health programs.

Copies of *A Review of Mental Health in Industry* can be obtained by writing to the National Institute of Mental Health, Public Health Service, Bethesda 14, Md.

The State of the Nation's

public
health
services

Abridged reports from the 56th Conference of the Surgeon General of the Public Health Service and the Chief of the Children's Bureau with the State and Territorial Health Officers, Mental Health Authorities, and Hospital and Medical Facilities Survey and Construction Authorities, November 3-8, 1957, Washington, D. C.

Building the Protective Wall

**By Leroy E. Burney, M.D.
Surgeon General of the
Public Health Service**

The record of public health in the United States has been established in great part through the individual and collective efforts of State and Territorial health officers. That record is an enviable one. To be sure, the people are not always as gratefully aware as we would like them to be of the hidden services which form a wall of protection around their families and communities. Just as surely, we who are occupied full time in the practice of our specialty are sensitively aware of the

gaps in that protective wall and the inadequacies of our resources. But, on balance, the informed but detached observer would be forced to the judgment that the public health system which covers the Nation has become a relatively efficient factor in the good life which this country enjoys.

Foreign visitors traveling now in the United States are much impressed with our home heating plants and washing machines, even with our mail order catalogs. I am positive that they are impressed, too, with the high degree of health protection which our people accept so casually in their communities and as they travel from State to State.

My appreciation, however, comes equally from the assurance conferred by experience that this same Federal-State cooperative approach and this same sharing of the load will continue to be the American way of seeking

better solutions for unsolved health problems and rational approaches to new problems.

A current example is the influenza vaccination program. From first alert to full-fledged operation has taken an amazingly few months. The manufacturers produced by December 1 more than 60 million cubic centimeters of Asian influenza vaccine—a good 2 months ahead of original estimates. Equally outstanding is the efficiency of our nationwide communications system and the competence of our specialists in public information and health education, which have made the American people active participants in a truly national effort.

There are many imperfections in the influenza vaccination program, as inevitably there will be in such large-scale operations. But preventive medicine has kept better step with the natural forces of an epidemic in this instance than it has ever been able to do in the past. At no time was it claimed that we could stave off the epidemic from this country. Nor was it claimed that the program was initiated in the guise of a defense against mortal illness. But we are just now beginning to see the more serious attacks occurring in older age groups and other high-risk groups which show a higher mortality rate. As the vaccine now becomes more generally available, let us intensify our efforts to see that as many individuals as possible have the benefit of vaccine protection.

It seems axiomatic in the health officer's existence that he has never finished one urgent task before at least one more demands his attention. While we have been preoccupied with influenza, we dare not forget the partially won victory against poliomyelitis. An effective vaccine is available in adequate supply. Its use to date has produced remarkable reductions in paralytic poliomyelitis. But we cannot close this chapter until we know that the 80 million unvaccinated and partially vaccinated persons under 40 years of age have received protection before the next high-incidence season.

On still another front, we are faced with a host of problems each of first magnitude. Growing populations, finite natural resources, technological changes in industrial production and daily living—all confront us with self-

made threats to health and life, comparable to those previously offered by microbial hazards. Those who are surrounded by these problems need scarcely be reminded of the flat necessity of moving forward in water and air pollution control and, most emphatically, in radiation protection.

We have so much to learn in the realms of biophysics and biochemistry that we need expect no quick and simple answers to these questions. But by hard, unrelenting toil, we must learn more of the toxic effects on man—in long-continued, low-concentration exposures—of the many physical and chemical forces to which he is now exposed. We must also have increasing precision in the measurement and analysis of the physical and chemical components themselves so that we can define and evaluate existing exposures accurately.

From increasing biological and technical knowledge will come eventually standards of safety to which all can subscribe. And we must put the same intelligence which is producing man's new environment to work in devising the means to hold those standards. Meanwhile, we must do whatever we can to reduce excessive concentrations harmful to man's health and safety. For while we recognize the necessity and the values of new factors in modern life, they must be kept in balance if man is to realize his ambition to continue to exist in reasonable health and happiness.

We have made some progress toward this objective in nationwide programs to cope with water and air pollution. Public health, however, has not yet taken its proper place in radiation protection. The increasing medical and industrial uses of fissionable materials place this responsibility in the realm of community health protection, since these major sources of exposure are the common experiences of life and work, rather than the extraordinary and occasional experiences related to military operations.

As I look through the agenda for this conference, I find some old familiar items. But a comparison of topics year by year very surely shows us the trends of our concern.

We will be discussing the topics I have already touched upon. We will be concentrating even more vigorously on training activities.

We will add improving steps to things we have done before.

An example of the latter is the improvement of working relationships in the field of records and statistics. I note with considerable satisfaction the report of the Joint Committee on Vital Records and Health Statistics which offers solutions to certain problems in the maintenance of comparable data and uniform records in our national and State programs.

Finally, we will be discussing with greater emphasis the problems of chronic disease control and health of the aging. This year grant-in-aid funds have been made available to help surmount some of the financial barriers that inevitably block the development of new and unfamiliar projects. The reports we have received from the States on their plans for the use of these funds are encouraging. They indicate a real beginning toward the comprehensive, balanced programs that will not only attack the major causes of disability, but also will make life healthier, happier, and more meaningful for millions of our older citizens.

Public health must take the lead in changing that intolerable and unnecessary situation of having tens of thousands of persons in the richest nation of the world deprived of the very high quality preventive and rehabilitative services which it is now possible to provide. I am pleased to see that you are taking up this challenge by devoting a considerable portion of your agenda to nursing home operations and other equally practical and down-to-earth aspects of this problem.

Very crucial to the development of better services for the chronically ill and to all of the newer programs that concern us is the question of how to organize them within our existing community structure.

There is always a greater lag between a new concept involving human relationships and its support by the public than between the discovery of a "miracle drug" and public acceptance. How then do we modernize our public health structure at the point where it counts most—the local health agency? We are fortunate indeed at this conference to be able to draw upon the personal experiences of local health officials who have successfully answered that question. Those of us in Federal and State

agencies have much to learn from local officials, who are at the delivery point of public health services.

As always, the plans we make together will affect the lives and welfare of all our people. But now we must plan in a setting, on the one hand, of greater and greater demand for vast expenditures for military defense and world security, and, on the other hand, of a growing realization that there must be some reasonable limitation on taxation and government spending.

We work as usual within these constricting factors. We will feel them even more within the next few years. But we can never forget our responsibility to keep the Nation aware that its defense, its security, its hopes for world peace depend primarily upon a healthy and vigorous people protected in their homes, schools, workplaces, and communities by health services sufficient unto the day of a new and changing world. We know that without the work of the Nation's health agencies there will be less to defend and less with which to do it. From this inner conviction we must draw the strength that keeps us to our tasks.

Grants-In-Aid Reappraised

By John A. Perkins
Under Secretary of Health,
Education, and Welfare

My remarks are concerned with a fundamental problem of American government that has been much debated since the days of Hamilton and Jefferson. In 1908, Woodrow Wilson declared the question of the relationship of the States to the Federal Government to be the "cardinal question of our constitutional system." It still is.

Public health is where it is today owing in large part to the evolution of the Federal-State relationship in the last 30 years. The new Federal-State relationship, heralded in the 1930's as the "new federalism," was brought about largely through the grant-in-aid device.

There were definite weaknesses among the States that these grants—matching, stimulatory, and other varieties—were initiated to overcome. The complexities of 20th century urban life seemed to require legislative and administrative action with respect to public health, safety, and welfare. These areas of public activity were not delegated to the Federal Government. They were reserved to the States.

A few commonwealths, generally the wealthier ones, did enter upon social legislation, regulation, costly research, and other concomitants of modern government. In these States, industry and citizens found some of their individual and corporate freedom reduced in order to promote the health, safety, and welfare of the people as a whole.

Industry and citizens either sought sanctuary, or threatened to do so, in other States which had fewer regulations and lower taxes. In the poorer States modern services could be financed only with the greatest difficulty, if at all. Capacity to tax in support of such governmental services varied greatly from State to State. Even where there was the wealth and a fairly satisfactory revenue system, the legislature did not always understand the wishes or requirements of the people. Many of the legislatures were not really representative because they were not properly reapportioned as State population patterns changed. They did not, and sometimes still do not, reflect the predominantly urban culture that has developed in the United States.

Then, too, in many commonwealths, executive authority has been diffused among the governor and a host of other elective State officials. Fixing responsibility for initiation of executive policy—or the failure to initiate it—has been difficult. It became increasingly evident that the extent and quality of some services of government, such as fighting disease and safeguarding public health, while local by fact of original Federal-State arrangement, were national in their consequences. The Federal Government had to act.

Grants-in-aid to the States administered by the Public Health Service were first introduced in 1918. This first grant, which was for venereal disease control, gradually dwindled to nothing

by 1926. Grants were not reinstituted for public health services until 1935 with the passage of the Social Security Act. Title VI of that act, administered by the Public Health Service, provided for general health grants. To this authority were added venereal disease control grants in 1938, and with the codification of Public Health Service legislation into the Public Health Service Act of 1944, tuberculosis control grants were authorized.

The year 1936 was historically significant for expansion of health and welfare services for children. The Children's Bureau, which from 1921 to 1929 had administered funds for maternal and infant health, was enabled under the Social Security Act to aid the States in greatly improving and extending services for maternal and child health, crippled children, and child welfare.

Subsequently, mental health and hospital survey and construction grant authority emerged in 1946, and heart disease control and water pollution control grants in 1948. In addition, annual appropriation language beginning in 1948 provided the basis for grants in cancer control and in 1949 for a special public health grant to the Territory of Alaska.

Grants for the construction of hospitals were extended in 1954 to other types of medical facilities. In 1955 came Salk vaccine; funds were made available to the States through the special poliomyelitis vaccination assistance program. In 1956 grants were made available to strengthen State and interstate water pollution control programs and to assist municipalities in the construction of waste treatment works. Also in 1956 grants were approved for a national mental health study, for vocational training of practical nurses, for further professional training of graduate nurses, and for a public health traineeship program. In 1957 Guam was made eligible for Public Health Service grants, and special grants were made for projects for mentally retarded children.

Every State now has a mental health program. In 1946, which was a year before the Federal Government started making grants-in-aid to States for mental health services, such programs were in formal existence in only seven States.

The Hill-Burton program has stimulated a

substantial volume of needed hospital construction, especially in low income rural areas. This Federal assistance to local hospitals has brought about improvement in standards of design and has indirectly improved standards of operation, through encouragement of State licensure. Federal support of specialized health programs has brought great benefits to the American people.

In the evolution of these grant programs, however, certain disadvantages have become apparent:

First, the grant process has so improved those functions of government which are of immediate interest and concern to the individual that people generally have felt little or no need to insist on correction of the weaknesses in the organization of State and local governments that helped to give rise to Federal intervention in the first place.

Second, the people most directly affected have, to a certain degree at least, been removed from the process of decision making.

Third, the grant process makes it difficult to relate the tax bill to the services received. Federal expenditures, expanded as they are by large outlays for defense, come to seem unconscionably high to taxpayers. Unfortunately, the taxpayer is not aware that much of the service he is receiving at the State and local levels depends to a considerable extent on the Federal tax he pays. If State and local taxes paid the whole bill for the services received on the State and local levels, the taxpayer could readily decide whether the services were worth the cost.

Fourth, the responsible expenditure of any public money requires certain safeguards to make sure that the money is expended prudently for the purpose for which it was provided. In carrying out this responsibility, Federal officials frequently encounter complaints that such safeguards constitute an intrusion into State and local affairs.

Fifth, one of the great advantages the Federal system of government offers has tended to atrophy. I believe it was Justice Oliver Wendell Holmes who spoke enthusiastically of the opportunities our Federal system affords for State governments to serve as laboratories where experiments in government might be made. State officials have been so busy carry-

ing out the many programs initiated at the national level that there has not been enough time for inventiveness and special adaptations to local requirements on State initiative.

Sixth, State budgets have been somewhat distorted by the matching process. There is a natural tendency in the State budget offices and State legislatures to finance those activities for which the Federal Government puts up part of the money. The maximum Federal dollars are usually sought whether or not there is sufficient money left to finance the functions wholly dependent upon the State and local governments.

These are some of the specific problems in the grant mechanism. There is a related phenomenon. Grants originated to stimulate a particular program have a strong tendency to become frozen into the pattern of State budgeting. The Federal Government may believe that one grant program has served its stimulatory purpose. It senses another area where greater activity is needed in the national interest. The logical thing in that case would be to drop or greatly reduce the first grant program, leaving the remainder of the job to State and local authorities. The Federal money thus freed could then go into the new activity needing attention. But it is not quite that simple. There is a danger that when Federal money is withdrawn the States will not make up the difference.

In addition to these basic questions, there are now other circumstances that suggest reevaluation of the grant system. Sums required to maintain our military strength and that of our allies constitute a large burden on the national budget. A great many of the special taxes levied during the war are still with us. Those who would have bigger, better, and more grant-in-aid programs cannot with very good logic also demand that the Federal Government slash taxes and surrender tax sources to the States.

If State and local government is to be made as strong as all seemingly would have it, two things must be done. First, State and local administrators of government must be alert to emerging problems. In the field of public health, this means facing and solving such prob-

lems as those of the chronic diseases, the hazards of radiation, and economics of medical care, to name a few.

Second, we must so educate and inform our citizens on the importance of progress in public health that they will not be satisfied with anything less than the best programs possible. Here in the support of the citizen-taxpayer lies the secret of how to build sound and progressive public health programs. It is to your credit and that of State and local appropriating authorities that State and local funds for public health have been increased an average of 47 percent in the last 5 years. Some States have increased appropriations more than 100 percent in this period. In fact, State and local expenditures for public health, not counting maternal and child health programs, have increased from 74 percent of the total to 93 percent of the total since 1940. This record of what has been done in the past portends well for what can be done in the future.

I want to make it crystal clear that I am not calling for abandonment of the grant-in-aid device. There is, of course, a strong national interest in public health. Federal grants-in-aid have proved to be an effective means for furthering that interest and for smoothing out, at least on a minimum basis, the variations in wealth among the States. However, I am suggesting that realities of today's world and its demands on the Federal budget require that the States and local communities assume an increasingly greater part of both the burden and the challenge presented by the public health needs of the future.

Children in a Changing World

By Katherine Brownell Oettinger
Chief, Children's Bureau

A number of factors now influencing our national life and economy call for a great deal of vision and adaptability in the future direction of the Children's Bureau programs.

A demographic factor with particular significance is the sharp and continuing rise in our

young population. This increase in the number of children is already taxing our services, most evidently in the schools, but also in the areas of health and welfare. Obviously, health and welfare services must be expanded to match this population increase even quantitatively. It is of particular concern to us because for this age group so much of the work is preventive in nature.

The rising cost of medical and hospital care—indeed, the rising cost for providing most of the services which are our concern—call for a high degree of administrative ingenuity in all our programs. In my opinion, such ingenuity must always be coupled with a program to promote understanding of the importance of the services we, as health and welfare workers, are giving.

We are indeed in an era where we must all run very fast in the same place, and yet I know how dedicated you are to the principle of progress, of steadily building on the basis of new program concepts, of putting new knowledge to work as it becomes available.

I can think of no more vivid example of the States' desire to make progress than the way they have responded to the impetus of a small amount of special project Federal money to develop community programs for retarded children. As of now, 28 States are receiving these special project grants, and plans for 3 more States are in the process of approval. The grants for these 31 State projects total \$1,338,530 for the current fiscal year. In addition, five other States are financing mental retardation programs with regularly apportioned Federal maternal and child health funds and State and local matching funds.

This speaks eloquently for your inventiveness and experience in the development of maternal and child health demonstrations. That it was accomplished within the space of 1 year in the face of recruitment difficulties and our lack of experience with clinical services for mentally retarded children adds to the stature of your achievement.

We all know that parents of retarded children have been the primary moving force in developments in the field of mental retardation. Parents are always a strong force in a democracy, and they represent a group to which

the Children's Bureau is responsive. The impetus to these developments presents fresh evidence of the contribution which citizens can make. This is one more chance that traditionally comes to the Bureau to put democracy to work.

Developments in the field of mental retardation are again proving the validity of the "team" approach in children's services. In these services, a number of States have developed effective working relationships among departments of health, education, and welfare, and involving parent groups as well. Of particular interest to us also, in connection with these project grants, are those projects now being carried out by medical schools in which practicing physicians, medical students, and nurses are gaining working knowledge about mental retardation. Our future medical graduates will have a much better understanding of retardation than generally exists at present.

In these few months in the Children's Bureau I have been impressed by the vast impact which the three categories of grants the Bureau administers—in maternal and child health, crippled children's services, and child welfare services—have had on the development of services for children in many States and localities.

Through the administration of its grants programs, the work of its regional offices, and annual conferences such as this, the Children's Bureau can stay constantly aware of changing conditions in State and local health and welfare programs to which it must be sensitive if it is to be responsive to the needs of mothers and children.

Trends in Child Health

We are all heartened by the emergence of a broad concept of rehabilitation in health, education, and welfare agencies. I speak now of rehabilitation as "making the best with what one has." This concept involves optimum social, emotional, and physical restoration, as well as the prevention of progression of disability.

One example of this trend is the increased interest in programs of service to child amputees. At the area amputee center at Grand Rapids, Mich., for instance, the project staff are making possible the rehabilitation of extremely handicapped children, with results which so far have

been notable. As you know, the services of this clinic are available to a child amputee needing such specialized services from any State.

A cooperative venture on the part of the University of California at Los Angeles, the California State Department of Health, and the National Research Council, aided by a grant from the Children's Bureau, has made possible the child amputee research project at the University of California at Los Angeles. Here, particular attention is being given to the technical aspects of fitting children who are amputees, as well as to the psychological and social aspects. They are asking such questions as: How do children respond to prostheses? When should a child be fitted for a prosthesis? What is the best way for him to learn to use it? How does the congenital absence of an arm affect his growth and development? What defense mechanisms do parents develop to gain better acceptance of the prosthesis by both child and parent?

Incidentally, the Children's Bureau was able for the first time in 1957 to gather some information on the prevalence of amputations among children. On the basis of reports submitted by crippled children's agencies in 25 States, it would appear that about 1 percent of all children served in those programs lacked one or more limbs or parts of extremities.

We also see a trend away from long-term hospitalization for the child, and toward helping the family in providing care in the home. This trend in medical care programs is paralleled by a trend in child welfare programs which places increased emphasis on helping children in the setting of their own families, wherever this is practicable.

In the tremendous increase in hospital deliveries we are finding both problems and opportunities. The problems seem to center around the quality and quantity of available medical care: problems which may be accentuated in the light of our increasing birth rate.

But in the increasing interest in classes for expectant parents, evidenced all over the country, we have an opportunity to lay the groundwork for the promotion of mental health in families.

Information from the first revised maternal and child health report now coming into the Bureau shows that the increase in the number

of mothers and children receiving service under these programs continues. Three facts stand out:

- Some 10½ million children received the Salk vaccine under maternal and child health programs in 1956.

- Last year 2½ million children received audiometric testing. This is the first time we have information on the number of children tested under these programs.

- Some 296,000 children received medical services last year under the crippled children's program, an increase of 6 percent from the previous year. Congenital malformations continue to make up the largest group of diagnoses, representing almost a fourth of the total.

Last month, a group of radiologists, obstetricians, pediatricians, dentists, and public health workers met with the Bureau to advise with us on radiation hazards to mothers and children. Both this Association of State and Territorial Health Officers and the Association of Maternal and Child Health and Crippled Children's Directors were represented. The pediatricians and obstetricians attending this meeting reported that doctors in practice and in medical schools recognize the need to take positive steps to make sure that in its very proper role as a diagnostic tool, there is no excessive use of X-ray.

It seems equally important for us to examine our own practice in our clinics to be sure that routine does not become a larger consideration than the exercise of the physician's best clinical judgment in the use of X-ray.

Now, as to some of our related interests in which medical professional groups are devoting increasing attention:

For the eighth consecutive year, reports show a rise in juvenile delinquency which, percentage-wise, is faster than the increase in the juvenile population. Interest in State and local programs for the control and treatment of juvenile delinquency continues at a high level. Several States have established new services, and a number have either proposed or passed legislation which provides for changes in State structure to permit establishing separate agencies or divisions to administer services to delinquent children.

There is also considerable activity in the establishment of new or reactivation of old State and local committees or commissions for communication, joint planning, and coordination of services and activities in relation to juvenile delinquency. Forestry camps have already been established in at least 10 States, with 5 others planning to establish such camps.

Maternal and child health services can be a strategic point for preventive efforts in juvenile delinquency. Studies show that some children at the ages of 9 or 10 manifest pre-delinquent behavior which could be noted in a good school health program.

As Norman Lourie has said, "We are aware that the so-called delinquent youngster . . . must have been deprived of something terribly important to him as a human being if, in order to be at peace with himself, he has to be at war with society." Strengthening family relationships during the earliest stages of the child's development could perhaps do much to offset this kind of deprivation. Well-baby clinics offer the natural setting for the discussion and strengthening of the developing mother-child relationship.

We must recognize that, among the young in our population, the adolescent is a neglected figure from a health standpoint. We have concentrated our concern for children on infants and very young children, and much useful knowledge has been developed for them which is in effective use.

It seems to me that we must increasingly adapt our health programs to take into consideration the concerns of adolescent youth which are not similar to those of younger children, and are not yet adult concerns. Adolescents have characteristics peculiar to themselves.

We need to give thought to how we are caring for adolescents in our hospitals, and whether the guidance clinics which are available to meet their anxieties, both real and fantasied, are truly responsive to their needs.

In our school health programs, we need to assure the adolescent adequate counseling on health problems rather than relegate the student's contact with that service solely to an examination for athletic participation.

In many instances, the problem of obesity in adolescence is being treated as a part of the

young boy or girl's "growing pains," when, in reality, it may be the starting point for a life pattern which can best be checked when first observed.

It is unfortunate that so much of the attention we direct toward the adolescent age group today is in the form of concern for those adolescents who are delinquent. I think we need to be concerned with adolescents as an age group with health and psychological problems, problems of finding their way in the world.

One of the greatest challenges we face today is helping teen-agers find their place in this changing world. I have implicit faith in the parents of this country, who are trying to do a good job in preparing their children for tomorrow's world. I am sure they will welcome any assistance that we in the helping professions can give them in making that preparation adequate for the testing days ahead.

Trends in Child Welfare

In child welfare programs, points of view are changing and experimentation is taking place in the use of foster care. Specialized foster family homes are being tried for children formerly believed to require institutional care. The present trend in institutional care is away from large institutions for neglected and dependent children and toward small group homes to meet special needs of emotionally disturbed children and of adolescents who are not able to assume closer foster family ties.

The Children's Bureau for the past 2 years has employed a special consultant concentrating on unprotected adoptions. Any examination of the reason for these adoptions—black market sale of babies, gray market or other independent placements—points to the lack of adequate care for unmarried mothers. This lack seems more acute since the rate of illegitimate births is steadily rising and the mothers are increasingly younger. A large number are only 14 or 15 years old.

In 1957 and 1958, our special consultant has been working to find ways to bring doctors, lawyers, and social workers together, in planning for more adequate services for unmarried mothers and in identifying the respective roles of these professions in adoptive placement.

Work on the statement on the role of the social worker in adoption is well under way.

A statement of the doctor's role, adequately publicized by medical groups, could be an enormous help in clarifying the attitude and the activities of physicians who place babies today.

We plan to seek the help also of lawyers in developing the third part of this total picture of professional services in adoption.

The Children's Bureau has long had an active interest in homemaker service as a way of maintaining family living in times of crisis. As the result of a meeting called by the Children's Bureau in June 1956 persons interested in homemaker service recommended that a conference be held this year.

However, interest in this service is so great, and it has such wide application to problems such as care of the aged and chronically ill, as well as to children, that our original plans have expanded to include other governmental agencies and many national voluntary and public health and welfare organizations. The anticipated conference will be on homemaker and related services.

Working on planning for this conference is a steering committee with membership from the Children's Bureau, Bureau of Public Assistance, Bureau of Old-Age and Survivors Insurance, Office of Vocational Rehabilitation, Office of Education, and Public Health Service. The conference is now planned for late in 1958.

The problems of migrants continue to cause us concern. All of us in the Federal Government wish we had more facts, rather than guesses—just such simple things as counts on the number who migrate, on the number of children who go along, whether or not they get into school, are immunized, and get needed social services. The special projects in Colorado and Florida have flourished and must be a source of pride to the health personnel. We are especially encouraged by the initiative that the New York regional office of this Department has shown in getting people from States in the region together on a regular basis to exchange knowledge on activities and ideas. Plans are now under way, we understand, for a joint meeting between Region II and Region III to exchange views on common problems.

Dr. Eliot has always reported to you on the work of the United Nation's Children's Fund. In September, I had the privilege of serving as principal adviser on the United States delegation to the Executive Board of the United Nations Children's Fund, and of seeing Dr. Eliot in action. The tributes paid her at this final session after her long years of devoted service show how greatly she will be missed as the United States representative.

At the September session of the board, allocations of \$12 million were made to 80 projects in 53 countries or territories, bringing the total allocation for all purposes for 1957 to more than \$24 million. Disease control is the largest area of expenditure, with malaria at the top with \$8 million.

In recognition of the tradition of services of a high quality which have always distinguished the programs carried forward through the joint efforts of the Bureau and the State health departments, I hope in the years ahead we can continue to move forward with vigor in our role of helping the disadvantaged, of pressing for preventive measures, in continuing to enlighten the public in times which are constantly changing.

Social Security And Public Health

By **W. L. Mitchell**
Acting Commissioner
Social Security Administration

The Social Security Administration has been given jobs to do through congressional action that have important public health implications. As illustrative of the extent to which the Social Security Administration is already involved in health programs, approximately \$370 million was identifiable in 1956 as public assistance expenditures for medical care. Almost \$10 billion was paid out under our social security program, an aggregate that can be said to have public health implications if for no other reason than that personal well-being is inseparable from public health.

Payments under the old-age, survivors, and disability program are now at an annual rate of close to \$7 billion, and the number of beneficiaries has passed the 10.5 million mark. About 5.3 million people are receiving assistance totaling some \$2.8 billion a year under the four federally aided programs.

We in the Social Security Administration have been increasingly concerned about the interrelation of the service and income-maintenance aspects of our programs, and we share that concern with people in public health. Last year's amendments strengthened the welfare service aspects of the public assistance programs and helped the States to increase their medical programs. The effectiveness of the insurance program in meeting basic economic needs depends in many ways on the extent to which the community provides needed health, welfare, and related services, especially those which increase an individual's capacity for self-help and self-care. If the beneficiary is able to manage without major expenditures for special care, his benefit can more adequately cover basic costs of food, clothing, and shelter.

Since economic well-being is inseparable from social well-being, and since the dividing line between peace of mind and physical health is slight indeed, these programs cannot help but have tremendous impact on the health of all our people.

New Developments

Last year, Congress amended the old-age and survivors insurance program to provide cash benefits for severely disabled insured workers between the ages of 50 and 65. Earlier, in 1954, provisions had been enacted to freeze the benefit rights of workers who are totally disabled for long periods during their normal working lifetime. Well over half a million freeze applications have already been received. With cash benefits first payable for July 1957, it is estimated that about a quarter of a million persons aged 50-64 will be awarded benefits in the first year of operation. Disability benefits to be paid in calendar year 1958 are estimated at about one-quarter billion dollars. These benefits are paid out of a separate trust fund financed through a tax increase on employees, employers, and the self-employed.

To qualify for disability insurance benefits or for a disability freeze, it must be established that the insured worker has a physical or mental impairment that is so severe it keeps him from engaging in any substantial gainful activity. It must be the kind of physical or mental condition that shows up in the medical evidence, including the doctor's report, hospital reports, or special tests, and it must have lasted for at least 6 months and be expected to continue for a long and indefinite time.

The determination of disability is made by a State agency, usually the vocational rehabilitation agency, under an agreement between that agency and the Federal Government. The State agency staff, a medical consultant, and a lay adjudicator, usually with rehabilitation experience, make the determination on the basis of medical evidence and such personal and vocational factors as age, education, and work experience.

Health officers may be interested in some statistics from the operations of the disability provisions of the program. Of the cases adjudicated for benefits or a freeze in 1956, 85 percent were male. The median age of allowed applicants was 58.1 years and almost 65 percent were ages 50-64. In half the cases, the disabling illness had lasted 4 years or longer. Of all applicants allowed during 1956, 57 percent were in institutions or confined to their homes, and an additional 6.5 percent required help to get about outside their homes. These figures reflect the early adoption of procedures to identify severely disabled people. Institutional and home-bound cases were quickly identified and, as a result, were filed promptly.

Four classes of diseases accounted for more than three-quarters of the cases allowed in 1956: diseases of the circulatory system, including heart disease, about one-fourth; diseases of the nervous system and sense organs, about one-fourth; mental, psychosomatic, and personality disorders, about one-fifth; infectious and parasitic diseases, including tuberculosis, about one-eighth.

Through the 1956 amendments, Congress also extended benefits to the disabled child over 18 of a retired or deceased insured worker, provided the child had been totally disabled before age 18. It is estimated that about 35,000 dis-

abled children will be added to the benefit rolls in the first year. A surprising number of these children had been disabled for many years and were completely unknown to the community. In some cases, the filing of a claim for benefits may be the means of making the parent or guardian aware that resources are available to help this child to a more normal life. Thus the new benefit has significance beyond the mere provision of income support for adult children whose disabilities make them dependent.

Physicians and Disability Provisions

A practicing physician, serving on a part-time basis, is frequently the medical member of the State agency evaluation team that makes the determination of disability.

The family doctor who has attended the claimant is also closely involved. The disabled person, applying at his social security office for benefits or to have his record frozen, is responsible for getting the medical evidence needed to show the extent and duration of his impairment. Most of these individuals have had some medical attention and will ask their attending physicians to supply medical reports on their conditions. Others may take the report form to the clinic, hospital, institution, or agency where they have received treatment. While the medical report form was designed for the convenience of the physician, it is not required that he use this form; a narrative summary or photocopies of pertinent records are acceptable.

Mental institutions, sanatoriums, and hospitals for the aged and chronically ill have received more requests to complete medical reports than have general hospitals since a higher proportion of their patients qualify under the disability provisions. We fully appreciate that completing a multiplicity of forms creates an unusual burden on these institutions. We believe that they will be relieved of much of the problem when disabilities that had their onset a considerable time prior to application no longer form such a high proportion of the workload. For purposes of the disability freeze, applications have been accepted from individuals whose disabilities began as early as 1941. In these cases it is usually quite dif-

ficult to reconstruct reliable records. After June 1958, a period of disability cannot be established beginning earlier than 1 year from the date of the application.

One of our problems is to dispel some of the misconceptions that attending physicians have about their role in the disability process. Many doctors feel, and I suppose with considerable justification, that they should be reimbursed for the cost of preparing the medical report. We fully appreciate the feelings of physicians who ask for a fee when it is obvious from the patient's attitude that he does not expect to pay for the service. But, as a matter of policy, we require the applicant at his own expense to furnish us with records which reasonably support his claim.

Other doctors are perturbed when asked to complete medical reports for individuals whom they have not seen for many years. We seem to have great difficulty in getting over to them that the report requested is not intended to portray the present medical condition but relates to the medical condition at the time the physician last examined the individual.

In many cases, the medical evidence submitted is inadequate, and it is necessary to write back to the reporting physician. Many doctors believe that a simple statement of diagnosis, prognosis, and opinion as to the degree of disability is the type of information required. Actually, the determination of disability is made principally on the basis of clinical and laboratory findings. The applicant's doctor is not asked to make a determination of disability. We ask only for complete enough clinical information to allow a reviewing physician to evaluate effectively the incapacity and the probable future course of the condition.

The law requires that all disability applicants be referred promptly for State vocational rehabilitation services. Insofar as possible, the process of determining disability is geared to provide facts about the person's impairment and residual capacities that are also useful in identifying the kinds of services needed for rehabilitation.

By July 1957, 400,000 applicants had been referred. Case disposition reports had been re-

ceived in 140,000 cases. These reports show that only 7 percent of the applicants had enough potential for rehabilitation to be accepted for services. Since a very large proportion of the persons referred were in the older age group and suffered from serious and long-standing disabilities, we could hardly expect to find many vocational rehabilitation prospects among them. As the backlog of long-standing disability cases is eliminated and as the more recently disabled come to form a higher proportion of applicants to the Bureau of Old-Age and Survivors Insurance and, thus, of Bureau referrals, we may expect the practical effectiveness of the referral program to be greater than indicated by the data now available.

An immediate problem, however, is how the vocationally unrehabilitatable can be helped to realize their maximum potential for self-care and a satisfying life. Here is an area where much might be done through demonstration projects of services to disabled beneficiaries, perhaps with a State health agency assuming responsibility for the organization of the special services needed.

Public Assistance Medical Care

There exists a great variety of methods of providing medical care to recipients of public assistance. The methods differ not only from State to State but among the localities within the same State. Medical care for this group has been traditionally a local responsibility, but such responsibility is gradually being supplanted or supplemented by State programs and, to a lesser degree, by Federal grants-in-aid to the States. The Federal grant, by requiring statewide participation, is undoubtedly a factor in the extension and improvement of provisions for medical services to needy people.

Federal participation in the financing of medical care has, however, been very modest. While public assistance costs, including general assistance, are presently running at the rate of about \$3 billion annually, only about 9 percent of the total in calendar year 1956—\$269 million—was in the form of vendor payments made directly to hospitals, doctors, druggists, nursing homes, insurance companies, and so on. Of the total vendor payments, less than one-fifth was made from Federal funds. An-

other \$100 million was included in the money, or so-called cash, payment to recipients to give them funds to pay for medical care; perhaps as much as three-fifths of this amount came from Federal funds.

A large part of all vendor payments has been concentrated in a few States. Of the vendor payments made for the aged in June 1957, half were in New York, Illinois, and Massachusetts.

Until July 1957, Federal participation in medical care for public assistance recipients has been subject to an individual monthly maximum (currently \$60 for adults) which determined the Federal share of both maintenance payments and medical care. In 1956, Congress provided separate matching for medical care on an average basis. The average monthly amount in which the Federal Government will share on a fifty-fifty basis was set at \$6 for every adult and \$3 for every child on the assistance rolls.

Following the 1956 medical care amendment, 13 States have for the first time submitted plans as a basis for claiming Federal participation in the medical care payments in one or more categories of public assistance. In other States which have had established medical care programs, the ratio of medical care costs to total public assistance is rising.

The States that are now moving into medical care for recipients of assistance are those with the least economic resources. They, more than States with well-established programs, must examine their plans most carefully. These States especially need professional help in planning how best to spend an amount that is recognizably inadequate for the job to be done.

It appears that an ever larger portion of the dollar for public assistance will be spent for medical care. With the social insurance program carrying the burden of income support, public assistance will be increasingly concentrated on people with heavy medical needs.

Let us turn now to another development in which health and welfare people are jointly concerned: the possibility of restoring former mental patients to normal living arrangements after institutional care is no longer indicated. No one would argue about the desirability of arrangements that make it possible for such people, many of whom have spent most of their years in institutions, to participate again in a

normal life. But I think we should recognize that the joint efforts of our health departments and our welfare departments in making such arrangements may run into financial barriers involving total cost and how the cost is shared. The costs involved in returning a former patient to the community frequently include costs of basic income support to be provided through the Federal-State program of public assistance and always include costs of services for finding a suitable place to live and to adjust to a new way of life. In the long run, these costs may be no greater than costs of good institutional care. But their financial impact is different. Whereas the State budget had carried the full cost of the institutional care, the locality may now be called on to share costs, at least for services. And while the total cost borne by the State and its localities may be lower because of Federal participation in public assistance, the mere fact that some local financing is involved can prove an almost insuperable barrier.

Nursing home care constitutes another area in which we have a strong mutual concern. In the recent study of nursing homes in 13 States which the Public Health Service made jointly with the Commission on Chronic Illness, it was found that fully half of all proprietary nursing home residents were recipients of public assistance. Furthermore, assistance funds were paying the full bill in 4 out of 5 of these cases. In most of the States the average payment made to the nursing homes in behalf of recipients of public assistance was considerably below the private-pay average. This highlights a very difficult situation—the problem of financing nursing home care by public assistance at rates that will buy really good care.

Some welfare agencies have already recognized that it may cost less in the long run to pay nursing home charges that include restorative and rehabilitation services than to pay, over a much longer period of time, charges for care that merely permits the patient to live out his days in bed. The new public assistance provisions for medical care may make such financing increasingly feasible.

The welfare field must rely on the public health field for a large part of the task of seeing that these nursing homes are safe and sanitary and for improving their standards so that they

are more than mere depositories for human beings. Skilled nursing services, restorative activities, and adequate medical supervision are minimums which are sadly lacking in some of these establishments.

I feel that I speak for public welfare people in general when I say that public welfare agencies have no desire to become medical agencies. We believe that the department which is under medical auspices should have an important voice in developing the medical aspects of social insurance and welfare programs. We who are concerned with the social security programs are ready, eager, and willing to cement our partnership with those in the public health field. Through a truly cooperative endeavor, the competency of each can be brought together for the general well-being of our total population.

Charting the Growth Of Radiation Hygiene

**By Russell Morgan, M.D.
Special Consultant on Public
Health Aspects of Radiation
Public Health Service**

Public exposure to radiation is becoming a major concern of health agencies.

The major users of radiation may be categorized as medical, industrial, agricultural, governmental, and military.

The major sources of radiation may be classified as X-ray machines; other particle accelerators such as the betatron, which is coming to have increasing industrial application; natural sources, including radium and radon; radionuclides that have been produced or concentrated by the hand of man; nuclear reactors, including their fuels and wastes; and weapons.

The biological effect of radiation that has attracted particular attention in recent months is genetic, that is the disruption of chromosome material. Not only are damaged chromosomes in germ cells productive of changes in the future generation, but changes in the chromosomes of somatic cells are productive of

changes in tissues in the present generation. Such somatic effects may be cancerous in character. There is no question that radiation is related to the incidence of leukemia. And its life-shortening effects seem to be well indicated, if not precisely known.

The immediate task is to place radiation hazards in perspective in the total enterprise of public health. Studies have begun toward this end, and the information available is not all that could be desired to organize firm conclusions. Nevertheless, preliminary figures provide some basis of comparison between radiation injury and such disease entities as poliomyelitis, tuberculosis, heart disease, and mental illness.

It appears that, unless the present trend in gonadal exposure to radiation is checked, genetic injury may be expected to produce more deformities in future generations than have been suffered from anterior poliomyelitis. The health burden of radiation injury at present is roughly in the same order of magnitude as the burden of tuberculosis. In 5 to 15 years, unless adequate safeguards are instituted, the health burden of radiation injury may be close to that of heart disease. Radiation is unlikely to be as much of a burden on the health and economy as mental illness. But radiation hygiene will be significantly and substantially more important in public health practice in the next few years.

What programs may health agencies be expected to develop for radiation hygiene? The foremost need is for research in both fundamental and in applied radiobiology. Such research is needed to bolster standards of radiation safety. It is no secret that the maximum permissible dose limits that have been recommended are arbitrary judgments, based upon assumptions no less than upon facts. And only effective research can supply the facts to replace assumptions as the basis for reasonable, intelligent, and practical measures of radiation safety.

It is also important to develop a general understanding of the public health significance of the increasing number of radiation sources. Although excellent work has been done to explain the physics, the engineering, and the functional aspects of radiation, little has been done

to stimulate education in public health aspects of radiation. Such education, training, and experience is of course basic to the application of a program of radiation hygiene.

With respect to the regulatory aspects of such a program, it is a sound policy, accepted in most political institutions, that the agency which promotes an activity should be separate from the agency which inspects and polices that activity. For example, there is a current public conflict between the interest, economic and administrative, of promoting the construction of power reactors near centers of population, and the interest of public health. It is a responsibility of health agencies to protect the public health interest with respect to such projects.

Health agencies inclined to work on radiation hygiene are not necessarily at a loss for qualified counsel. In many universities there are men who have sufficient acquaintance with the physics and biology of radiation to provide the health official with guidance. A first step for a health department might be to prepare an inventory of people who are qualified and willing to help in these decisions. Another step is to develop an inventory of radiation sources within the agency's jurisdiction. And the surveillance of these sources will permit the agency to determine what needs to be done.

Progress Report on Air Pollution

By Vernon G. MacKenzie, B.S.

**Assistant Chief, Research and Development
Division of Sanitary Engineering Services
Public Health Service**

Air pollution, in its modern form, may be taken as a prime example of newly developing public health problems associated with increased urbanization, intensified industrial activity, greater use of transportation, fuel usages, and refuse disposal practices. Activities of this kind, connected as they are with modern urban living and a higher standard of living, are essential and beneficial to organized society; the problems they create, therefore, are strikingly

characterized by the fact that they are not solely detrimental to public health. And, too, unlike the older problems of communicable diseases, these new problems cannot be "stamped out." They must, however, be controlled and kept within safe bounds.

Several factors contribute to the increased complexity of the air pollution problem: changes in fuel usages, increased per capita use of energy, and increased per capita consumption of materials. A revolution in fuel usage has occurred in the last half century. In 1900, 90 percent of the fuel energy in the United States came from solid fuels; today, 70 percent comes from liquid and gaseous fuels. Equally striking has been the huge amount of energy made available to us, and the greater per capita use of raw materials and of finished products from them. Visible smoke pollution problems, which could be abated by relatively simple measures, have been superseded by the more complex problems of contamination by gases, vapors, and miscellaneous particulate emissions.

Air pollution problems are widespread throughout the United States. One survey has estimated that 10,000 communities in this country are affected by air pollution. The magnitude of local problems ranges from contamination produced by a single factory stack to "smogs" spreading and mixing over entire metropolitan areas.

Evidence of damage to livestock, vegetation, and physical structures by various air pollutants is reasonably well documented, although incompletely understood. Economic losses from such causes have been estimated at more than \$1.5 billion per year.

Equally well documented is the fact that air pollution can cause personal discomfort, such as eye and respiratory irritations, or even human illness and death under conditions unfavorable to the atmospheric dilution and dispersion of contaminants. Of perhaps equal public and professional concern, although without documentation, has been the potential long-range effect of pollutants on human health. Although the evidence of causative relationships between specific atmospheric contaminants and the effects upon humans is incomplete, the intensity of pollution has impelled undertaking air pollution controls in many areas even in the absence

of knowledge on specific etiological relationships.

Air Pollution and the Law

Local ordinances for the control of air pollution have long been a part of American government. The first smoke-control laws were adopted by Chicago and Cincinnati in 1881. Comprehensive control of air contaminants, however, is a recent development. The major impetus in the enactment of air pollution control legislation has come since World War II. In a recent study, it was found that more than 80 percent of the ordinances of 110 cities, representative of various population sizes, have been enacted within the last 15 years. Further evidence of the growth of local programs is afforded by the Directories of Governmental Air Pollution Agencies published in 1955 and 1957, the number of local agencies listed increasing from 115 to 279 in the 2-year period.

On the State level there has long been a history of sporadic ad hoc activity of technical study in connection with specific air pollution problems, principally by State industrial hygiene organizations. Recently, however, there has been increasing interest in the organization of State programs explicitly authorized by statute. The first of these laws was passed in Oregon in 1951. It established an air pollution authority in the Oregon State Board of Health with powers to study and legally enforce all aspects of air pollution. Similarly comprehensive legislation in Massachusetts and New Jersey followed in 1954. A State air pollution program was authorized in California in 1955 and in 1957 in seven additional States (Colorado, Delaware, Florida, Minnesota, New York, Ohio, and Washington) and the Territory of Hawaii.

The circumstances contributing to the enactments differ from State to State, resulting in considerable variation in the laws, and there has been but little operating experience under them. Several features of these laws, however, deserve mention:

1. All of the laws would apparently authorize studies and technical assistance for local problems.
2. Ten of the twelve enactments extend coverage to all air pollution problems; two would

restrict the authority to instances detrimental to public health.

3. Eight of the twelve laws provide for some legal control of air pollution on a State level.

4. In every instance, the State health department is named as the operating agency; in five instances, a board, commission, or authority is also established with interests other than health represented.

Only one legislative step has been taken in relation to an interstate air pollution problem. Under legislative authority enacted by the States of New Jersey, New York, and Connecticut, and ratified by Congress in 1956, the Interstate Sanitation Commission is studying the interstate problem in the New York-New Jersey area and will report to the legislatures of these two States.

If there is any lesson to learn from the history of State and local air pollution control legislation to date, it is that the individual law or ordinance should be tailored to the situation and take into consideration the varying circumstances and needs of the jurisdiction involved.

Public Health Service Program

The Public Health Service program on air pollution, authorized by the 1955 act, is now in its third year. The act authorized a 5-year program of research and technical assistance at a maximum annual cost not to exceed \$5 million. It specifically reserved to the States and local governments the responsibility for legal control of air pollutants. Approximately \$8.5 million has now been appropriated under the act, \$1.75 million in 1956, \$2.75 million in 1957, and \$4 million in 1958.

The major emphasis in the program is on research. Approximately 80 percent of the resources are devoted to this purpose, and the remaining 20 percent are used for training and technical assistance on specific problems. From another viewpoint, approximately 60 percent of the available budgetary resources are devoted to physical science and engineering control studies and 40 percent to studies on the effects of pollutants on health. From a third viewpoint, about 45 percent of the program resources are used for intramural Public Health Service activities, with the remain-

der divided about equally between outside grant and contract studies. All grants and contracts are on a project basis; the act does not authorize general support or formula-type grants.

Although much of the research is necessarily of long-term character, some results are already appearing in reports and publications concerned with the identification and measurement of pollutants in the atmosphere, the factors affecting the behavior and dispersal of pollutants in the atmosphere, the effects of air pollutants, and means for their abatement.

Work under way on improved methods of analysis has led to a promising development for continuous monitoring of fluorides and an improved smoke inspection guide for use by local authorities. Other areas in which progress is being made include tracing pollutants to specific sources, filter fabrics for high temperature gas streams, and improved design for refuse incinerators.

The lack of basic data on the nature of air pollution has led to the creation of the National Air Sampling Network covering 110 urban and 25 non-urban sites. This network, operated in cooperation with States and communities, may provide data on air pollution which can be correlated with geographic, demographic, meteorologic, and other variables.

That part of the program concerned with the effects of air pollution on human health has initiated toxicological studies to determine the effects of pollutants on animals and biological systems, and clinical and epidemiological studies to determine the effects on human beings. The compilation and publication of mortality data by cause of death for 163 metropolitan areas have provided an important working tool for use in this and other fields of study. Another example of medical research recently initiated is a study undertaken in cooperation with the National Cancer Institute and the University of Southern California on the carcinogenicity of aliphatic and aromatic fractions of air pollution samples collected in eight metropolitan areas through the National Air Sampling Network.

In the 2 years since the initiation of the air pollution program, several hundred requests for technical assistance on general and specific air pollution problems have been received from

State and local government agencies and other organizations. The assistance provided by the Service has depended, of course, on the resources available and has varied from limited consultation to assigning personnel to work cooperatively with State and local agencies.

Staff members have been assigned to studies in the States of Connecticut, Washington, California, and Tennessee, and in Louisville, New York, Los Angeles, Philadelphia, and other areas. The cooperative State surveys which have been made in Connecticut, Washington, and Tennessee have, I believe, demonstrated a means of appraising the statewide air pollution problem at reasonable cost.

In addition to the direct technical assistance activities of the Service, demonstration project grants have been provided for study of local and regional problems. Such grants have been made to the State health departments of California, Colorado, Illinois, and Indiana, to the city-county health unit of El Paso, Tex., the Interstate Sanitation Commission, and Oregon State College. Other demonstration project grant applications are pending.

To assist in the alleviation of the shortage of technical personnel trained in air pollution research or control, the Service has been conducting short-term training courses at the Robert A. Taft Sanitary Engineering Center in Cincinnati; more than 500 trainees attended the training courses during the last fiscal year. In addition, the Service has made grants to 10 universities distributed across the country for initial development and support of graduate level curriculums, and for a limited number of traineeships.

With 2 years of the program completed, a considerable volume of results from the various studies undertaken are beginning to flow in. The Service hopes to make this information available at the earliest feasible date. Consequently, a more formal system will shortly be inaugurated for disseminating information derived from the Service's direct air pollution studies and from grants and contracts which it is supporting. Reports of a general nature together with lists of projects undertaken and other reports, publications, bibliographies, conference proceedings, and similar informational material will be available shortly.

COMMUNITY HEALTH SERVICES

At one of the conference sessions, three local health officers described activities illustrative of the theme "developing new local health department programs within existing community organization." Their papers follow.

Rehabilitation In San Mateo

By **Harold D. Chope, M.D., Dr.P.H.**
Director of the Department of
Public Health and Welfare,
San Mateo County, Calif.

Within the last 3 years, a forgotten part of the California county of San Mateo has been found, and what was to many a life without hope has become a life with purpose and dignity. The story that I tell, however, is not just of a few disinherited individuals who were provided for, but of an entire county that became involved with the problems and satisfactions of rehabilitation. For, upon a foundation of resourceful social and public health workers, community interest accumulated to form a bridge upon which all might walk.

San Mateo County is relatively small, covering 448 square miles on the San Francisco peninsula. It is bounded on the east by San Francisco Bay, on the west by the Pacific Ocean, on the north by the city and county of San Francisco, and on the south by Santa Clara and Santa Cruz Counties. The county is split down the middle by a range of hills which protects the eastern slope of the county from the chilling winds of the Pacific, and it is here that the population is most dense. On the western slopes are the sleepy little towns of Half Moon Bay and Pescadero, still supporting a way of life with fishing, cattle, and truck gardening not much different from the early days.

The people who live in San Mateo are young (the median age is 31.4 years), relatively well

educated, and have an income that averages \$1,400 higher than the United States as a whole. They form a community which in recent times has become increasingly urban, with light industry and decentralized shopping centers burgeoning about them.

The San Mateo Department of Public Health and Welfare, first established in 1932, is now organized into five basic divisions: administration, recently added to the department; public health; social service; county hospital, including outpatient and psychiatric facilities; and the tuberculosis sanatorium. The social service division operates two institutions, a 17-bed home for dependent and neglected children and the 135-bed Crystal Springs Rehabilitation Center.

The most extensive reorganization of the department has taken place since 1948 as a result of a complete survey ordered by the board of supervisors.

In 1948 the county faced many problems. World War II had prevented not only the normal increments in a building program but had made impossible the development of physical facilities to serve the rapidly growing population. While the department had many excellent employees, there was need for more employees, considerable reorganization, and the recruitment of new leaders in some disciplines. Much time during the first 4 years (1948-52) of the present administration was spent in construction, recruitment, and reorganization. The new addition to the Crystal Springs Home was completed in 1949. An entirely new 120-bed tuberculosis hospital was dedicated on March 2, 1952. A bond issue to enlarge the county hospital was approved by the voters in November 1952, and the addition was completed at the end of 1956. In 1953 the health and wel-

fare divisions moved out of the basement of the courthouse into a new 50,000-square-foot administration building on the hospital site.

Rehabilitation Begins

During this period there was considerable fomentation regarding rehabilitation, much of the stimulation coming from Dr. Lester Breslow, chief of the bureau of chronic diseases of the California State Health Department, but nothing that could be delineated as a formal rehabilitation program. While there was much reviewing of current articles, conferring, and verbalizing about rehabilitation, this amounted to little more than the fertilization of the soil in which our now beginning program was to grow.

I think that at this point it is only fair to point out that, while the desire for a rehabilitation program existed with the medical administrative personnel of the department, and various specialties in medicine have made major contributions, the real leadership came from the social work discipline.

Until February 1954, the Crystal Springs Home had been operated as a "relief home," with the "inmates" receiving "custodial care for elderly indigents." Adrian Ward, superintendent of the social service division at that time, recommended as the new manager Einor Nordby, a man with broad experience in social work. Mr. Nordby brought to his new job more than good training and broad experience; he brought two other characteristics of inestimable value: a strong conviction about the values of rehabilitation and an abiding faith in the infinite capacity of human beings to overcome seemingly insuperable handicaps and, I might add, a sincere respect for human dignity. Within a few weeks, the "relief home" had become the "Crystal Springs Rehabilitation Center," the "inmates," "patients," and "custodial care for elderly indigents" became "rehabilitation treatment services for patients with long-term illness."

While it did not take long to change names and terms, it took a little longer to develop the program and philosophy indicated by these terms and to teach a largely untrained staff to center their efforts on restoring dignity, status,

self-respect, and self-esteem in the individual patient. The dietary was improved after a survey by the nutrition section of the State health department. Little things were initiated, such as arranging the mealtime to suit the patients rather than the staff, placing sugar and condiments on the table to afford patients free choice of seasoning, providing a before-bedtime snack of graham crackers and milk, consulting patients on their likes and dislikes, and serving food as attractively as possible instead of prison style. None of these things alone had too much significance, but each indicated to the patients that the management considered them humans capable of personal decisions, with opinions of value in determining policy.

A second method of providing motivation to the patients was to form committees to discuss policy and program—a library committee, an occupational therapy committee, a patient's service committee. Budgetary limitations did not permit the employment of additional staff the first year of operation, so the manager and the committees turned to the community for volunteer help. The relief home had been shunned by the community, except for a few stalwart church groups and people "wanting to do something for the poor" during the holidays. But with the new spirit, which is hard to describe but was immediately felt, community organizations, service clubs, church groups, women's clubs, and others became enthusiastic sponsors of various rehabilitation activities, providing materials, tools and money, and finding qualified volunteer arts and crafts teachers. The patients exhibited their handiwork at the annual fiesta (county fair); they organized an annual bazaar and started a monthly newspaper.

These activities gave status and helped restore sadly depleted self-esteem. The "inmates" were again human beings with personalities and skills. These activities gave new hope and incentive, but this was not enough. The physically disabled were still disabled though their outlook had improved. The mildly depressed responded well, but the severely depressed were still depressed. Again volunteers were recruited—a psychiatrist, a half-time physical therapist, social workers in the evenings after their regular day's work.

Time does not permit a step-by-step development of the program through the next 2 years, but the demonstrated accomplishments convinced the board of supervisors, and we started fiscal year 1958 with a fairly adequate professional staff consisting of a part-time psychiatrist, a full-time psychiatric social worker, a part-time medical physiatrist, 2 physical therapists, 1 full-time and 1 half-time occupational therapist, 2 part-time internists, a part-time vocational counselor, a full-time dietitian, and a nursing director with a master's degree, experienced in care of the chronically ill.

What has this type of service cost the taxpayers of the county? Do the results justify the added expenditure?

The indigent custodial care, consisting of food, shelter, and minimal medical care, cost the county \$4.96 per patient-day for the fiscal year 1953-54. In the year 1954-55 the cost increased 54 cents per patient-day to \$5.50. In 1955-56 the cost went up another 50 cents to \$6 per patient-day, and in 1956-57 it rose to \$7.55 per patient-day. This represents a \$2.59 increase over the \$4.96 of 1953-54, or a 52 percent increase in costs. The cost increase is not all chargeable to rehabilitation. Increases in salaries, enlarging the nursing staff, rising costs of operation, and conversion of custodial beds to treatment beds account for most of it. The actual salaries for the professional staff associated with the rehabilitation program and the supplies and equipment amount to 45 cents per patient-day.

What did the county get for this? During the year 1956-57, 12 patients were restored to full-time employment, relieving the county of all financial responsibility ($12 \times \$2,756 = \$33,072$), and 41 patients were returned to private living in the community at far less cost than institutional care, a net saving of \$69,790.

These figures and calculations have value in budget analysis, but to me they are not the important results of a rehabilitation program. What criteria do we have to measure social value? What is the worth of human dignity to the individual? What is a new lease on life worth to a man who was totally defeated and contemplating suicide? What is it worth to his wife and family? What is the money value on the extension to 1 year or 10 years of active, in-

dependent, and productive living of a man who at 55 was rejected and disabled and felt discarded by society? Can society afford to rescue a woman of 70 from the living death of permanent bed rest with attendant evils of premature senility and retrogression to infantilism?

Subjectively, I am much happier to be responsible for an institution around which the community rallies, with the garden club planning landscaping projects, the cosmetologist association helping start beauty parlors, and church groups providing spiritual counseling, than to be responsible for the operation of a "poorhouse."

Broadening the Program

While the tangible and intangible rewards of expanded institutional care were many, there was still much to be done for those outside the institutions: the recipients of general assistance. Again we called on our State health department for a study to review programs and outline the needs for medical social workers. In September 1954 we established a medical social work service.

A study of the general assistance recipients in the county revealed that about 58 percent were dependent because of alleged poor health. This seemed to be a serious indictment of a department which had available all of the modern facilities for prevention and treatment of physical illness.

Although many were receiving care in the outpatient clinics of the department, it was decided to employ an internist in February 1955 to give thorough physical examinations to public assistance recipients and to serve as liaison between the social workers and the outpatient staff.

In a review of the work, 16 months later in June 1956, it was found that 75 percent of the men examined fell into five diagnostic categories: chronic alcoholism, chronic pulmonary disease, hypertensive vascular disease, neurological disease, and orthopedic defects. The women presented a different picture: 40 percent had a diagnosis of psychoneurosis or psychosis, and 23 percent had no diagnosable disease. It was obvious that physical health alone was not a major cause for the recipient's dependency. With these findings we approached

our psychiatrists in the adult psychiatric clinic. They declined to participate on the basis that the volume of cases was too large for them to handle and that the recipients would be uncooperative and unamenable to therapy. Although not accepting the recipients for individual or group therapy, the psychiatrists did consult with the rehabilitation team.

In September 1955, a part-time vocational counselor started testing the recipients, and the team in a staff conference attempted to summarize all data on each recipient and to rate the recipient as to potentiality for rehabilitation according to five factors: motivation; physical condition; skills and abilities; personal adjustment, including intelligence; and social adjustment. Using a scale of A through E for rehabilitation potential, we found that exactly 50 percent of the patients studied had a rating sufficiently high (A, B, or C) to justify further efforts.

As we moved along in this study, we observed that some of the patients, although appearing to have rehabilitation potential, had suffered such a long series of tragic experiences and had endured these experiences for such a prolonged time that they had come to accept passively their dependency and disability role. Many had tried to get jobs and had been rebuffed or had failed so many times that they no longer had the courage to seek a job or the confidence that they could hold one if found. So in October 1956 we started a work experience program. This was not the kind of a program where the clerical worker is put to raking leaves or picking up beer cans in the public parks. After the vocational counselor had delineated the possible skills of the recipient, an effort was made to place him in one of the county departments for work experience or he was referred to the California State Department of Vocational Rehabilitation for training. Mechanics were put to work on the county cars; women with sewing skills, in the linen rooms of the institutions; and recipients with clerical skills, in the various offices of the county. This relatively sheltered and planned experience was sufficient in a surprising number of cases to convince the recipient that he was able to work productively, and many sought and obtained private employment.

Our most recent step, in August 1957, was to

establish an industrial rehabilitation workshop under the direction of a trained occupational therapist.

Our next anticipated step is the formation of a citizens committee with representatives of labor, management, civic groups, local government, and interested persons to see if we can further our rehabilitation process.

Implications for Others

State and Territorial health officers might well ask, "What has all of this to do with our programs?" What has been reported is an isolated incident in an unusual type of administrative setup which exists only in this one small county in all of the United States.

But let me summarize the implications for State health officers implicit in this case report.

1. Specialized consultation (statistical studies, nutritional studies, and social service consultation) is available on the local level from State health departments.

2. If public health administration is to pursue vigorously the now accepted objectives of reducing chronic diseases and improving mental health, that segment of our population on welfare rolls presents a rich field for administrative study and the development of techniques.

3. Successful rehabilitation will not be accomplished by any single discipline but by a careful synthesis of the contribution of many professional disciplines: the psychiatrist, the social worker, the vocational counselor, the physician, including the specialist in psychiatry, and the administrator.

4. Results in rehabilitation may be accomplished by using the time-honored techniques of public health administration: careful delineation of a problem, selection of a specific segment for early efforts, locating, employing, and supporting well-trained staff, utilizing community resources, obtaining budget and financial support for the project, and keeping the community informed of progress. A local health officer does not need an administrative organization such as ours to further rehabilitation. A health officer, for example, in a county south of San Mateo has done an outstanding job with the traditional organization.

In the field of rehabilitation we should constantly keep in mind that beautifully confused metaphor of Charles Chapin: "It is not for me to 'set the river afire;' but there is many a great edifice builded of small stones."

Improving Patient Care In Nursing Homes

By **Herbert R. Domke, M.D., M.P.H.**
Commissioner of Health
St. Louis County, Mo.

Achieving improved care for nursing home residents requires coordination of many services, professional groups, and agencies, a function that is uniquely suited to the health department through its legal responsibilities for inspection and its pivotal position in the community.

As an inspection agency the health department can collect information on patient care and nursing home operation which may be a basis for developing programs.

As a formal unit of government, the department is in a favorable position in helping formulate proposed legislation.

Through its work with all nursing homes in a jurisdiction, the health department can help the nursing home operators, individually and as a group, develop professional understanding that can lead to improved techniques of patient care and other aspects of nursing home operation.

The health department, because of its relationships with other governmental and voluntary agencies, can foster varied community services related to patient care and adjustment. A special activity may be interpreting more accurately to the community the nursing home's role in meeting problems of the aged and chronically ill.

In Missouri, the St. Louis County Health Department, through its nursing home inspection program, acts as agent in enforcing State nursing home legislation in the county. From this basic service, the program has branched out into research, legislative, and training activities.

In comparison with national data the nursing homes in St. Louis County are reasonably typical. Data by age distribution, type of medical and nursing service needs, and financial support show that county homes and patients are in the median range for the United States. There are 15 nursing homes with less than 10 beds and several with more than 100 beds. The majority are privately operated; some are under church or other charitable sponsorship. The 60 homes in the county have a total bed capacity of more than 2,000, a larger number of homes and beds than would be expected for the St. Louis County's 600,000 population. The disproportionately large number is almost certainly the result of an enforcement code adopted by the city of St. Louis more than 30 years ago. The county had no licensing program until the State adopted its first nursing home legislation in 1941.

Legislative Action

The nursing home program, along with other aspects of chronic illness and aging, has received considerable attention in the community. Much of this program carries out recommendations made in a survey of chronic illness published by the St. Louis Social Planning Council in 1946. Also, in 1953 a Missouri nursing home association sponsored a bill designed to correct many obvious deficiencies of the 1941 law. However, the bill did not pass.

The health department began emphasizing the nursing home program early in 1954. At that time its official governing body, the St. Louis County Council, provided funds for establishing a chronic disease control section, partly to expand the existing, inadequate inspection. Acting on a recommendation of the Social Planning Council, the county council also authorized a survey of all nursing homes and their residents. The survey, utilizing the Commission on Chronic Illness forms, provided much new information.

Precise survey data pointed up defects and inadequacies of existing State legislation, further supporting the legislation sponsored by the nursing home association. In 1955, the association-sponsored bill, slightly modified, was reintroduced, and with broader backing

was approved by the State legislature. Unfortunately, the bill contained a provision which was held unconstitutional. In 1957, impelled by the disastrous nursing home fire in Warrenton, Mo., the legislature amended the licensing and regulation bill, which is now the basis for regulation.

The most controversial part of the present act provides for licensure by the type care the resident needs. The survey made by the Commission on Chronic Illness was especially valuable in supporting this provision because it showed a wide range of patient needs—from essentially boarding care to medical and nursing services at almost hospital level. For the first time in Missouri, it is possible to define minimum nursing home standards appropriate to a realistic appraisal of patient need.

Probably no one code can be a definitive answer to legislation and regulation, but this bill already has markedly improved patient care. Without the background of legislative review before the Warrenton fire, revised legislation would possibly have been restricted to fire safety provisions.

Survey of Nursing Home Residents

The Commission on Chronic Illness survey provides information about the resident's medical and nursing needs. Many other concerns, however, are expressed by the resident, his family, and the community.

Nursing home facilities continue to expand despite a general tendency to consider the home as an undesirable, last resort solution to the individual and family problem. Although there are some studies of psychological and social adjustment of the aged, including those in nursing homes, adequate information is not available on the factors important in placement and adjustment of the resident to the home. Certainly we had no such information in St. Louis County. More data were necessary to develop programs such as family counseling.

In 1955 a further special study of county nursing home residents became possible. Its purpose was to ascertain the circumstances leading to the use of the nursing home as a patient's way of living, the response of the patient to the solution of his problem, and any change that

might be made in him or his living arrangements that would restore or maintain him at his maximum level of functioning and happiness.

This study was jointly sponsored by the Chronic Disease Division of the Public Health Service, the Brown School of Social Work of Washington University, and the St. Louis County Health Department. General research policy was formulated by a committee of personnel from the three agencies. The school assumed responsibility for the execution of the project by its graduate students.

A sample of 36 residents from 23 different homes was selected for intensive interviewing. Residents interviewed were restricted to those who were clear of mind, had lived in the nursing home for a year or more, and had at least one close relative living in the St. Louis metropolitan area.

Detailed interviews of the resident, his relative, and the nursing home operator were conducted. Aside from the specific criteria of selection, analyses showed that the residents were essentially representative of the nursing home population when compared with the Commission of Chronic Illness data. Although the extensive interviews are a major asset, the small size of the sample can only represent a pilot study and the findings are not definitive. This unpublished study was compiled into one volume and presented as a joint master's degree thesis for many 1955 graduates of the school. The following discussion covers only a few of the factors studied and reported in the thesis.

The policy committee approached the study with certain preconceived ideas as to what it might find. Members thought many residents would totally dislike nursing home living, that relatives did not visit regularly, and that residents missed diversional activities. In this respect, the committee probably reflected the general community attitude toward nursing homes.

With due consideration for the small sample size, it is interesting and significant that these assumptions were not borne out. For example, 32 of the 36 residents, almost 90 percent, were found well adjusted on the basis of interviews with the resident, the relative, and the nursing home operator. Only 4 could be judged dissatisfied and had had a deteriorating course

of adjustment. Another set of data on psychological change in the patient after entry showed that approximately 1 out of 6 was improved, 1 of 5 was worse, and the remainder showed no change. Nursing home placement did not appear to have been generally deleterious for patients.

Although 8 of the 36 were entirely satisfied with their placement, and some of these 8 did not wish to return to a living arrangement with their families, the majority were only accepting of nursing home placement or had hopes, frequently unrealistic, of making other arrangements.

Data on Patient's Background

While these findings were certainly better than we anticipated, the background and expectations of the person who becomes a nursing home resident should be further evaluated. One surprising finding reflected in the favorable responses was that the women, who outnumbered men 4 to 1 in the sample, had had an unusual incidence of hardship as adults. Approximately 40 percent of the women had to assume complete financial responsibility for self and family at some time during their mature years, usually when they were widowed. This and other data indicated that the lower socioeconomic group in this community was more likely to select nursing home placement. Generally all the data pointed to the placement as an appropriate solution for the resident and his family.

Another finding was that the patient or family frequently did not consider a nursing home placement until shortly before the decision was made. Adequate preparation and participation of the patient in the decision to move to a home appears to affect directly his adjustment. The resident was much more likely to be satisfied if he and the family had sufficient time and information to decide. Residents who were only accepting of the nursing home, or who were dissatisfied, had done less adequate planning, and the resident himself was frequently not involved.

In more than half the cases where the patient was not entirely satisfied, he was not consulted, or had known of the decision for less than 2

weeks before it was made. This implies that individuals and families are not adequately informed about nursing homes, and the community needs a better understanding of the services which they provide. The generally unfavorable reputation of nursing homes may well cause delay in considering them as a solution.

Operators' Attitudes and Training

The study attempted to assess the nursing home operator's interest and attitude toward patients and also sought the resident's attitude toward the operator. The residents had almost uniformly favorable comments about the operator. Residents believed the operator was interested in their welfare, and all were highly disappointed that the operator did not spend more time with them. In general, the information obtained indicates that the operator plays an important, positive role in the resident's adjustment to the nursing home.

Interviews with operators indicated that their primary concern was the physical aspects of care—keeping residents clean, properly fed, and protected. Social aspects, such as keeping residents occupied and combating boredom and discontent, seemed secondary. Although physical care was emphasized, this usually did not include rehabilitative efforts. Occasionally the expense of rehabilitation efforts led to negative attitudes toward rehabilitation work.

The operators' attitudes may well reflect the emphasis of official inspection, which has explicit standards for a home's physical facilities and medical and nursing care. But, at least in the Missouri legislation, other aspects of operation which may influence the resident's adjustment to the home get little attention.

The operator's attitude is also affected by his background and training. In St. Louis County a few homes are managed by physicians, some by nurses, and one by a trained social worker. Most operators' educational background and preparation do not include professional training. Some have had only a high school education. Although inspections influence the service provided, the nursing home operator is ultimately responsible for his institution and the care of its residents.

Improved patient care can come only when

the operator has a more complete understanding of patient needs and of the background of official requirements. Improved care requires also that appropriate techniques be known to the operator.

Certainly the nursing home operator requires many skills which he now has little opportunity to develop except by unguided experience. The operator's varied, and not always adequate, training for his job and his importance to the resident point to a serious program need. Although nursing home associations recently have begun to provide needed professional information, there are not now adequate training programs. Regulation and inspection are of great value, but a considerable area of nursing home operation remains outside the scope of legislation.

Training for operators is, we believe, one of the most important activities the health department can initiate to improve patient care. The St. Louis County Health Department for the past 2 years has sponsored a monthly training program for operators. These programs, planned with a committee of the operators, have reviewed available professional knowledge on a wide range of topics such as fire prevention, nutrition, and cost accounting. These voluntary meetings have been well attended and seem to be one way of increasing the professional knowledge of nursing home operation. Aside from their informational function, they allow operators to share their concerns and trade ideas.

Conclusion

The nursing home program developed by the St. Louis County Health Department with other community agencies includes collecting information and research, legislative programs, and operator training. The program stems from the department's legal responsibilities as the licensure and inspection agency.

Specific features of the St. Louis County program may not be adaptable in other areas. Our experience, however, indicates that the community, the nursing home operator, the patient and his family, and official and voluntary agencies see the program as an appropriate health department function.

Surgeon General Leroy E. Burney in a recent

address to the convention of the American Nursing Home Association stated:

"Good administration, both within an institution and in licensing agencies, should be based on education and assistance, rather than on compulsion. . . . Standards and regulations should be in the form of basic principles, rather than an outline of specific details.

"Administrative difficulties, both in individual institutions and in public agencies, will not be satisfactorily resolved until the people of all communities accept nursing homes, in fact as well as in theory, as an integral part of their health services."

It seems to us that the health department can and should play an important role in achieving this goal.

Home Safety In San Jose

By Dwight M. Bissell, M.D., M.S.P.H.

Health Officer

San Jose, Calif.

In 1949 the city of San Jose, Calif., established an emergency first aid station and gave the health officer responsibility for administering it. Records were a necessary part of its operation. As we looked at the reasons that caused people to seek service, we were struck by the number of persons who had suffered accidental injuries. We were aware of the frequency of automobile accidents and of industrial accidents, but somehow we had never realized that such a large number of accidental injuries could occur at home.

We looked at the death records and found that year after year in our city of slightly less than 100,000 population 13 to 15 deaths were registered as due to home accidents. Few people had been interested in the fact that accidents were the third cause of death in our city, as they are in many other cities in California. We had a chapter of the National Safety Council, but it was interested primarily in industrial and traffic accidents. We knew that the National Safety Council was interested in home accidents, and we felt that the local chapter would be a natural ally in our concern about them.

Our health department personnel, numbering about 70, always work well together after we arrive at a group decision and agree on a program. We talked the home accident problem over at our division chiefs' meeting and decided to find out the degree of interest among those who would be working on this new problem. It seemed logical that nurses who visit families in their homes would be able to do some work in prevention of home accidents; that sanitarians who deal with housing and check on environmental sanitation of the home would be able to assist, too. Health education and vital statistics services would certainly be essential, and all of our epidemiological and administrative skills would be needed for a full-fledged attack.

When the subject was first presented to the public health nursing division, one nurse said, "Everyone has home accidents so what can we do about it, and why worry about it?" This comment gave us an opportunity to suggest that each of us record the accidental injuries occurring in our homes for a week or two to find out what really happens. Before the recordkeeping period was over, there was much discussion about the things that cause home accidents and about our unsafe environment. We began to hear comments about the number of home accidents. Environmental hazards seemed to be lurking everywhere. The experience produced convincing evidence that home accidents happen to all of us and that there are things one can do to prevent them. Most of our injuries, incidentally, were cuts and falls.

Community Participation

We have never tried to solve public health problems alone in San Jose. We believe that everyone who is interested has a right to share in planning and activities.

Each of us began to search for individuals or groups interested in home accidents. A number of insurance companies, we discovered, had a vital interest, and some of them were already active in this field. Some 30 industries were concerned, we learned by calling personnel directors together. Industry loses money every time a worker is absent from his job. He may be replaced, but the new worker is usually not

as efficient as the old one. One large industry employing 3,000 or 4,000 men had a home accident prevention program "on the books." By bringing attention to that program, the industry was able to develop a more realistic one.

Another group that became interested in home accident prevention was the Apartment House Owners Association. Fewer accidents in the apartments would mean lower insurance premiums. PTA groups, welfare groups (particularly those serving old-age pensioners), and health agencies were others among a total of about 70 groups finally invited to send representatives to a meeting to discuss organization of a program to prevent accidental injuries in the home. Pediatricians naturally had a leading role, but dentists, surgeons, clergymen, and many others were also interested.

We had some doubters in this group too, but exploration of the matter convinced them of the value of preventing home accidents. In fact, one of the original opponents became the strongest supporter. He "sold" himself by asking questions. It was easy to sell those agencies that could see a financial gain in preventing home accidents. The social workers, for example, quickly realized that their aged patients were much more expensive to the county welfare fund when they had to be cared for in bed than when they were ambulatory. The PTA members realized that they could protect their children's health better if they knew how to prevent the many cases of poisonings, burns, cuts, falls, and other accidents characteristic of growing up.

Accident prevention is a matter of personal health, and some of the people working with this program almost became neurotic about the subject. Because of the emotional and personal aspects of these preventive activities, the program had a stimulating effect on every person involved. Disability and death were constantly evident. One could hardly mention home accidents without 1 or 2 people in the group relating a personal experience with a home accident. Identification of an individual or an audience with the problem was easy to establish. The death of a small boy from eating ant poison shocked the whole community into the realization that home accidents are extremely impor-

tant. Education projects in classrooms evolved from this incident, and teachers began to feel responsibility toward preventing home accidents as well as school accidents.

Our community group of 70 decided to organize, with the assistance of the health education division of the health department. Four active work groups and a steering committee were set up.

Initial Problems

Inquiring minds began to ask about the definition of terms, and definitions became a stumbling block for a time. The words "home" and "accident" had different meanings for different people.

Another problem was establishment of a baseline against which a statistical measure might be used to determine the value of the project to the community. With only a limited amount of money for this task and our desire to accomplish something, we did not establish a baseline satisfactory to some statisticians. We thought we had appropriate data, but we found on analysis that they were quite inadequate.

Death certificates are of limited value in determining the number of deaths from home accidents. For example, in our city the greatest number of such deaths are among people over 60 years of age, and the cause is generally a fall. Did the elderly man have a stroke and fall, or did he fall first, causing an injury to his head? Did the person with osteoporosis fall because of the thinning bone or because of the slick floor? Did the elderly man with a fractured hip who died of pneumonia 4 months after the injury die of a respiratory disease or from an accident? What was the intent of the person who took an overdose of medicine? Was it accidental or suicidal?

Morbidity data are even more likely to be inaccurate than mortality data. With rare exception, most of the morbidity figures I have seen for home accidents have been estimates. Some household sampling has produced results of apparent accuracy, but even these are still open to question. However, all of the statistical inaccuracies should not frustrate one completely. The data do give one a general idea as to causation and frequency.

What Can You Do?

Once we had acquired as much background data and information about the occurrence of home accidents as we could, our question to each of the 70 committee members was, "What can the organization you represent, or you yourself, do about preventing accidents?" If time permitted, I should like to enumerate all the extremely worthwhile projects these men and women suggested and carried out. Some were short-range projects aimed at maintaining interest; others involved long-range planning.

During the 5 years in which the Kellogg Foundation helped support our home accident program, we experienced all of the stresses and strains to which a health department is accustomed. Personnel who were working full time on the project changed. Even the health officer was gone for a year. Some excellent ideas failed to work out as planned. Inservice training programs were tried. Various methods of community education were used in this experimental project. Language barriers were encountered by foreign-born people.

Evaluation Efforts

The one question that we felt we must answer was, did the project do any good? Did it prevent home accidents in San Jose?

There is no known way in which an accident prevention program such as ours could be evaluated completely and specifically, for there are too many factors at work in a community: the local and national press, radio, and television, as well as experiences of neighbors and friends, to mention but a few. A 20 percent increase in the population during the 5-year period meant that many families had moved into the city and were exposed to accident hazards caused by a change in residence. There were changes in jobs, and many new industries were introduced. All of these factors had not only a physical impact but an emotional one as well. It would be difficult to claim that a particular event produced a particular result. Our own personal actions in preventing home accidents are produced by a mosaic of experiences.

What did the figures show? Because of the unreliability of available data, we did not give much credence to the death certificates, which

showed that accidental deaths decreased considerably. Approximately the same number of home accident cases were being treated at the first aid station after the program as before, but our population was increasing and people were discovering the value of the station. We decided that perhaps another type of evaluation would be of greater importance than a statistical one.

We asked each of the persons who had volunteered to work in the program what he thought about it. Did the home accident prevention material help teachers to teach children about safety? Were the pamphlets prepared by our health education division of assistance to pediatricians and physicians in teaching parents about accident prevention? We were asking for an honest evaluation, for an opinion, of the total project. The evaluations varied greatly, as each one considered the accomplishments from his own point of view.

We also evaluated the program by the requests that we had for literature. We have had requests to permit reprinting of our pamphlet on prevention of accidents in childhood from many private physicians and local and State health departments in the United States. I am sure that these reprints would now total well over a half million.

Integration With Regular Programs

On June 30, 1956, the 5-year program ended, and our home accident prevention activities were integrated into the regular activities of the health department. We have continued to record and code services in this field. We have continued to provide health education services wherever we can.

One cannot introduce a new health program to a hard-working staff without advising them of work priorities. This process means that something must be dropped. The activity that is dropped depends on the interest of staff workers as well as on that of supervisors and administrators. Consequently, inservice training is an important function if home accident prevention activities are to continue. Few schools of nursing or schools of public health emphasize adequately the need for accident prevention activities.

Recently, I asked some of our staff members to be specific about what they were doing in

accident prevention. Some were spending a considerable amount of time on school safety, infant safety, or safety in the home. It was interesting to note that four nurses who had been employed in the last 3 months and had not completed their inservice training in this field were not nearly as aware of either the problem or the methods of teaching as the persons who had had experience during the home safety project. Each person must demonstrate to himself that accidents can be prevented and that they are important in public health whether a particular health department or voluntary agency recognizes it or not.

General Observations

In summary, I should like to offer a few generalizations in this matter of accident prevention.

Accidents occur because of an individual's relationship to his environment. During infancy the degree of protection must be extremely high. The wise parent gradually lessens this protection and gives the child more and more responsibility as he is able to accept it. The question that faces every parent is, how much protection should a child have at each age? How much protection should the community supply even to adults? Under normal circumstances an adult with reasonably normal behavior gets along fairly well until chronic disease or old age begins to lessen his physical ability to compete with the natural hazards of living. It is then necessary for him to be surrounded again with an increasing amount of protection until he may require complete protection before his death. Thus accident prevention becomes a study of growth and decay.

Accidents occur because of man's emotional reaction to his environment. Mental health problems today present the most difficult challenge for us in public health to assist large groups of people. The distraught, disorganized mother with many children and no assistance in supervising them is going to have more home accidents than the one with equanimity who can instill a feeling of independence and assurance in her offspring. The choleric individual will have more accidents than his equanimous neighbor.

Public health's problem is how to immunize the person whose reaction to his environment

may cause accidental injuries. In some individuals emotional imbalance is temporary; in others the usual behavior pattern is conducive to accidents. Both types need insight into their problems, and usually they require assistance in acquiring that insight.

Immunization for a person with normal behavior may consist of having an accident, then asking himself what he should do to prevent the next one, and finally taking reasonable, logical action as a result of his self-analysis. Unfortunately, many people who have numerous accidents do not take an analytical approach. Consequently, the epidemiologist must ask such people, "How did the accident happen?" "Why did it happen?" "What do you think you can do to keep it from happening again?"

It should be recognized that environmental factors can play a role in the causation of accidents. A slippery bathtub, a ragged carpet, an unlighted stairway, and many other things may contribute to an accidental injury. But it is always much easier to blame something or somebody than it is to look at ourselves and admit that we were at fault.

Because almost everybody has a few accidents each year, it is difficult for the health department to develop an effective accident prevention program. What we need is a way to concentrate our efforts on those families that are having the greatest number of accidents. Our problems are case finding and identification of the accident repeaters. We are engaged at present in a research project sponsored by the National Institutes of Health, Public Health Service, to devise a method by which a health department can find families who have a high incidence of home accidents.

With limited health department facilities, it is extremely important that the problem of case finding be solved. Until we have improved our skill in finding high-incidence families, our efforts will be as disseminated as were those against communicable diseases before the epidemiology of these diseases was established. Prevention of accidents depends on finding persons who are causing accidents to themselves and their families. With the problem thus identified, accident prevention will be within the capabilities of an average health department.

Gains in Industrial Safety

The loss of life in occupational accidents has decreased from 17,000 to little more than 14,000 a year in the last 15 years, according to the *Statistical Bulletin of the Metropolitan Life Insurance Co.* (October 1957).

Many industries have improved their safety records. The transportation industry provides a notable example. The occupational death rate for trainmen of all categories, as a group, dropped from 136.2 per 100,000 in 1939-41 to 47.3 in 1954-56.

In the past 15 years, workers in the petroleum industry have reduced by more than two-fifths their on-the-job accident fatality and permanent total disability rate. The rate for all departments combined dropped from 31.9 to 18.0 per 100,000 between 1939-41 and 1954-56. Part of the improvement is attributable to technological advances.

Similarly, in the chemical industry, the introduction of automatic machinery in many

operations has apparently lessened the exposure of workers to accident hazards and toxic materials. The chemical companies show a drop of nearly three-fourths in the rate of fatalities and permanent total disabilities during the years under review.

Several of the more hazardous industries have likewise made noteworthy progress in lowering fatal accident rates. The accident death rate among coal miners has decreased from 230.6 to 166.7 per 100,000 in the last 15 years. The lumber and electrical industries appear to have reduced their fatal injury rate by approximately one-third during the same period.

Much more remains to be accomplished, particularly in industries which have lagged behind in promoting safety programs. In addition to the 14,000 lives taken annually, 2 million workers are injured in accidents arising out of and in the course of employment.

TRAINING PROGRAMS

for **Milk Plant Operators**

NICHOLAS A. MILONE, M.S.

EMPHASIS has been and is placed on the need, value, and methods of instruction of food handlers other than those concerned with milk processing. If the published literature is used as the criterion, however, not much has been done regarding the education, training, and motivation of milk plant operators and owners.

Several reasons may account for the general lack of training programs for milk plant operators. The chief reason appears to be a current trend toward considering the sanitary objectives of milk control as a *fait accompli*. Tending to negate this assumption are some recent findings. Among these are a recent paratyphoid B milkborne outbreak incriminating pasteurized milk, equipment controls, and the human factor (1); laboratory thermal resistance studies indicating that heating *Coriella burnetii* suspended in whole raw milk for 30 minutes at 143° F. is insufficient to eliminate

all viable rickettsiae, suggesting thereby the need for tighter supervision of the pasteurization process (2); newer developments in the design and operation of high-temperature, short-time pasteurizers (3); the necessity for additional thermal resistance data on "no hold" and similar high temperature processes (4); and the closely associated need for the development and redesign of automatic time-temperature controls adapted to the demand of newer processes for quick response.

In addition, the New York State Department of Health recently compiled data to explain the causes for underpasteurization, which had been averaging 1.15 percent in New York State since 1949 (5). This department attributed the causes to (a) delegation of responsibility for pasteurization to unqualified relief operators, (b) change of management, (c) labor turnover, (d) moral and mental deficiencies of the operator, and (e) carelessness. Experience has shown that the human element may be considered the most important stumbling block to sanitary needs.

Nor should a casual statement to the effect that many more or less important intentional and unintentional violations of local, State, and Federal sanitary code regulations take

Mr. Milone for the past 8 years has been a resident lecturer in environmental health at the School of Public Health, University of Michigan, Ann Arbor. From July 1930 until June 1949 he was a sanitarian and bacteriologist for the New York State Department of Health.

place daily in many plants cause eyebrow raising among the initiated. In fact, considering the complexity of the modern pasteurizing process it would be surprising if such were not the case. From this standpoint, one cannot escape the strong suspicion that some potential outbreaks are avoided by the now common practice of overpasteurization.

Although there is considerable justification for holding management responsible for the proper operation of plants, health agencies cannot and should not miss the opportunity of promoting the spread of information as to the causes, nature, and prevention of prevalent diseases and the preservation and improvement of health. Certainly most will agree that relying solely on the punitive approach leaves much to be desired.

There is little doubt that existing defects in equipment and operation in milk plants may be attributed to some lack of training, education, and motivation. In an attempt to fill this need, the writer, with the cooperation of the health jurisdiction and milk dealers concerned, presented training programs in applied dairy and sanitary science to the plant owners, managers, operators, and personnel of Washtenaw County (March 13 to May 1, 1956) and Calhoun County (October 12 to November 16, 1956) in the State of Michigan. The 6-week course in Calhoun County was essentially the same as the Washtenaw County 8-week course with the exception of minor details.

Our experience, tailored to suit particular needs, may serve as a guide for other control agencies and dealers interested in the cooperative development of similar courses.

Preliminary Actions

At the initial meeting, the milk dealers were represented by owners and managers and the local health department by the public health engineer, educator, and sanitarians. We decided to hold the meetings each Tuesday evening at the Ann Arbor and Marshall Court Houses from 7:30 to 9:30 p. m. for 8 and 6 weeks. All plant personnel were invited to attend on a voluntary basis since they would be contributing their own time. The dealers agreed to bear the bulk of the expense. The

course was designated "Applied Sanitary and Dairy Science," the term "dairy" being used to indicate that the instruction would not be confined to sanitation.

A public health educator was assigned the task of publicizing the program by means of newspaper, radio, and television. The dealers reacted favorably to this aspect of the program, believing it demonstrated the dealer's concern for the consumer's welfare.

Objectives of the Course

Main objectives of the course encompassed the following:

1. To familiarize the trainees with the properties of milk and milk products and the various environmental hazards that may affect quality and safety during the production, processing, storage, and transportation stages.

2. To interpret for the participants the intent and applications of sanitary regulations as exemplified by the Ordinance and Code of the Public Health Service.

3. To inculcate in the trainee desirable mental habits relating to contamination potential of product, equipment and operation, product quality and safety, cleaning and sanitation, plant layout and product flow, and liability and responsibility.

A list of the subjects presented in the course is given on page 56.

The necessary motivation was supplied by continually pinpointing the relationship between quality and economics.

Presentation of Subject Matter

Throughout all sessions it was of utmost importance to present the subject material effectively and to establish the critical awareness desired. All the material is amenable to an interesting approach if properly planned, prepared, and executed. The use of visual aids prepared by the instructor plus judicious selection of available aids helped enormously in making the program a success. For these reasons a few of the devices developed and used will be described. To help attain and maintain a high level of interest, many references to experiences were made, some of a humorous, many of a practical, nature.

General subjects presented during the training sessions

Basic fundamentals

Science of milk production
Nutritive properties
Microbiology Disease and quality
Performance and quality

Receiving of milk

Deck tests Receiving equipment
Clarifiers Filters Separators Milk waste
Milk transportation Bulk tanks

Heaters and coolers

Exchange equipment Homogenizers
Pasteurizing equipment Pumps
Bottle fillers and cappers
Temperature and time controllers
Construction, design, and operation
Inspection and maintenance

Sanitizing equipment

Bottles, cans, and equipment
Bottle and can washers
Water, detergents, and sanitizers
Tests for determining efficiency

Sanitary quality control

Laboratory tests Trouble shooting

Defects in market milk and cream

Causes Solutions Routemen and quality

Plant layout, design, and utilization

Product flow
Building and building facilities

Legal aspects for the dealer

Liabilities Responsibilities

[Detailed descriptions of course content and the methods and materials used may be obtained upon request from the author. An instructor's guide containing lecture notes and use of materials is in preparation.]

At the start of the first session, a bottle of milk was placed on the table in front of the instructor. After remarking on the simple appearance of the liquid and how easily it could be simulated by suspending some bolt chalk in water, he projected on the screen a chart showing in detail the components of milk. This action served as a dramatic means of impressing the audience with the great complexity of the product they worked with daily.

A nontechnical movie, *The Science of Milk Production*, sponsored by the Purina Company of St. Louis and made in cooperation with the University of Minnesota, was then shown clearly illustrating how the cow makes milk. The motion picture was very effective and maintained maximum interest throughout its presentation.

One of the main aims of the training program was to make the trainee "contamination conscious." A series of placards was especially prepared to fulfill this course requirement. The placards described and illustrated the intimate life of a microbe, the decomposition of an apple, and the decomposition of a dead cat (*C.*).

In the first of these, pertinent references were made to the ubiquitousness of microbes, their never ceasing activities, the absence of a tem-

perature regulatory system illustrating an important fact which makes refrigeration possible, the factors limiting growth, their small size, enormous numbers, amazing appetites, astonishing variety of diets, rapid multiplication under favorable conditions, and finally the fortunate fact that the majority of micro-organisms are not only innocuous to humans but are actually helpful and necessary.

The sequence on the decomposition of an apple traced the organic breakdown of an apple from the moment it falls from a tree to its ultimate decomposition by soil bacteria.

The last sequence, the decomposition of a dead animal, detailed in nontechnical terms the decay and final disintegration of the animal body.

Petri dishes containing sterile nutrient agar were then passed around, and the trainees were asked to talk, expectorate, sneeze, and cough over the exposed medium. One participant was asked to draw his finger over the surface of the agar and another to place a hair on the surface. Following incubation the resulting cultures were projected on a screen and discussed.

At this point it can be stated without equivocation that the trainees had been made, in varying degrees, "contamination conscious." A few

judicious and qualifying remarks avoided establishing a microbiophobic turn of mind. Ever present was the temptation for the instructor to go overboard in making a point and thus do more harm than good. The other procedures used to obtain the desired mental habits were presented in a similar manner.

Public Health Service slides (7) and motion pictures (8), illustrating lecture material, emphasized construction, design, and operation in nontechnical terms.

The subject of sanitary quality was explored by demonstrating the tests commonly used to measure quality, together with interpretation of results. Methods of overcoming causes of unsatisfactory results were discussed in detail.

At the conclusion of this session a chart containing, anonymously, the yearly performance data of each participating dealer was projected on the screen. By this means, it could be effectively demonstrated that unsatisfactory results could be overcome by efficient performance.

The demonstrative method was used almost exclusively during the washing and sanitizing session which included a discussion of the advantages and defects of common methods.

The plant session covered building, lighting, ventilation, product flow, and many other aspects that tend to make the plant more efficient and economical to operate. Examples were given of legal implications, and the responsibility of the dealer to consumers was stressed.

The session on defects in market milk and cream covered causes and means of overcoming the defects. Concrete and factual examples explained sanitary code regulations.

At the last session of the program a succinct summary touched on the major points of the course, with some emphasis on the economic phases.

Audience Reaction

Previous experience had indicated that dealers would be hesitant to ask questions during the question period held at the conclusion of each session, believing that such an action might reveal vulnerabilities to competitors. For this reason, a question box was used for depositing unsigned questions which were discussed at the following session. Another means employed

was the use of a health department representative to ask leading questions.

From observations made throughout the program, and from those obtained at the conclusion of the course from an interview with the participants, the following information was elicited:

- Dealer reaction was very favorable.
- Most of the plant personnel attended all of the sessions. This was as gratifying as it was surprising especially in view of the voluntary attendance arrangements. As a consequence the audience as a whole gained a general knowledge of the contents of the course while the specialized crews benefited from the specific instruction directed to them.
- The session on defects in market milk and cream was the most popular, a reflection of one of the main interests of the dealers. Since quality and safety are closely related, this attitude cannot be considered a drawback to the main objective of the program.

- There were strong indications that desired mental habits were instilled in the trainees.

Requests to present the program in other jurisdictions indicated that there is a market for these programs. It should be thoroughly exploited because of obviously inherent rewards. Qualified instructors for such programs are available in each health department and institution of learning.

Finally, it is considered wise to reemphasize that one of the most important prerequisites for success in the presentation of these programs is to make a continual bid for interest. This can only be accomplished by a vast amount of time, thought, effort, and initiative in planning, preparation, and presentation. Ingenuity will help considerably. The rewards, however, make it all worth while.

Critique

It may be felt that the subject matter presented within the allotted time was too extensive and intensive for maximum effectiveness, but our chief objective was to determine the need, value, and reception by industry of the training course. The general complexity of the subjects makes it mandatory to present them over periods consistent with the attainment of maximum effectiveness. Any jurisdiction presenting these programs that finds the suggested

course lengths unsuitable may adjust the time factor to its particular needs.

An important consideration for evaluative purposes is the fact that one such program is not sufficient to the needs of the participants. Milk technology is in a dynamic state and progress is being made daily in all its phases. Progress should by all means be communicated to the industry, and the most satisfactory means of accomplishing this is by the routine and continual offering of training programs, properly spaced so as to accommodate new material as it becomes available.

Accordingly, these programs should result in material gain for the processor, and, in conjunction with its inspection and laboratory programs, the control agency should obtain benefits not otherwise realizable. The consumer, for whom all this work is done, would profit in the greater protection which this means of communication achieves.

Summary and Conclusion

Contrary to popular conception a challenge still exists in the dairy field and will persist for some time to come. New processes and new developments continue to evolve and with them new problems requiring solution.

Trial training courses were conducted for milk plant operators in Washtenaw and Calhoun Counties in Michigan to evaluate the need, value, and reception of such training. The course subjects ranged from basic fundamentals in milk processing to legal aspects for milk dealers.

The results indicated that such programs on a continuing, routine basis would definitely aid and be appreciated by the industry. The responsible agency and the public would profit in the greater likelihood of a high quality, safe product.

Surplus Copies of PHR

A limited quantity of back numbers of *Public Health Reports* are available free of charge to readers who wish to fill in their files. Surplus issues in stock are January through July and December 1953; April through December 1954; September through December 1955; January through July and September through December 1956; and January through July and September and October 1957.

Please address requests for copies, specifying month and year, to Public Inquiries, Public Health Service, U. S. Department of Health, Education, and Welfare, Washington 25, D. C.

Helping the Housewife Prevent Accidents In the Home

A. L. CHAPMAN, M.D.

DURING 1956 about 28,000 people died from the effects of home accidents, and accidents of all types were the primary cause of death in all age groups from 1 to 35 years.

In comparison with the community reaction evoked by heart disease, cancer, poliomyelitis, and mental illness, the community reaction to accidents has been conspicuously weak. With the exception of the National Safety Council, some State and local safety councils, and a small number of pioneering State and local public health officials, few agencies have given accident prevention the emphasis it warrants. Perhaps a feeling of helplessness has fostered this lack of emphasis, but with the growing acceptance of the fact that at least 80 percent of accidents are caused by what people do or by what they fail to do, public health workers are in a better position to exert leadership in accident prevention.

Since they stem from the actions of people, accidents can be made the subject of study, analysis, and prevention in the same way that human factors involved in the susceptibility of humans to disease have been studied.

The magnitude of the research effort that will be needed to develop scientific data of sufficient quality and quantity to support scientifically valid efforts to control accidents will be great—no smaller, certainly, than the magnitude of the research effort now being made to determine the causes and means of preventing cancer, heart disease, and mental illness. Meanwhile, much can be done on an empirical basis to accelerate the present slow but steady decline in accident rates.

There is presumptive evidence, at least, that

Dr. Chapman is chief, Division of Special Health Services, Bureau of State Services, Public Health Service.

intensive as well as extensive efforts to organize communitywide education programs can contribute to a marked decline in the number of deaths and injuries resulting from home accidents.

Group Conferences

Since face-to-face, person-to-person communication is more apt to motivate people to act than communication using the printed word alone, the usefulness of the group conference technique is suggested.

Several reasons may be cited for limiting the use of the conference technique to housewives during the early stages of the development of a local accident prevention program:

1. Experience with the group conference technique has indicated that housewives are more conscientious in attending conferences than men.

2. Although many mothers now work, the great majority still remain at home during the day. As housewives they play a "guardian" role with respect to the children in the household and to oldsters as well.

3. The maternal instinct can serve as a source of motivation to influence the mother to attend group conferences on accident prevention and to apply the lessons learned there.

4. Group conferences can be fitted nicely into the framework of orthodox public health operations in most communities since many public health nurses already are skilled in group conference techniques. Public health nurses are accustomed to working with mothers.

Booklets on Accident Prevention

The Division of Special Health Services of the Public Health Service has available two booklets that can be used in conducting local group conferences in home accident prevention. These booklets will be released through the regional offices of the Department of Health, Education, and Welfare to State health departments for final distribution to local health departments.

The first booklet, entitled "One Way to Develop Local Home Accident Prevention Activities," describes the development of these activi-

ties. Four stages are suggested for introducing to public health workers or to housewives the principles and techniques that are important in the prevention of home accidents. Stage 1 provides for a series of weekly conferences at which subject matter contained in the second booklet may be discussed; stage 2 describes methods by which local resources may be identified; stage 3 gives three methods for determining the extent of the local home accident problem; and stage 4 lists eight typical activities that may be engaged in locally to provide experience and seasoning.

The second booklet, entitled "Home Accident Prevention Text," presents a digest of principles and techniques important in developing home accident prevention activities. Sixteen chapters describe the accident prevention

problem, the various factors which contribute to accidents, and the roles that can be played by public health workers and physicians.

The guide and the text can provide local health officers with a useful digest of current material on home accidents, plus an organized method of presenting it to members of their staffs and then, through group conferences, to key persons in the community. Both booklets may be used to orient housewives to the problem of home accidents and to methods of preventing them.

The task of involving thousands of professional public health workers and millions of citizens in an all-out attack on accidents is a tremendous one. It can only be accomplished by attacking the problem simultaneously on many fronts.

Potential Anticancer Compounds

New, potential anticancer compounds will be produced by six research organizations under contract with the Public Health Service. The chemicals to be synthesized under these contracts are designed to interfere with the growth of cancer cells in various ways.

One group of compounds, known as antimetabolites, inhibits the growth of cancer cells by blocking certain metabolic reactions. These compounds bear enough resemblance to needed chemicals to be accepted by the cells, but they also differ enough to interfere with the cells' metabolic processes of self-repair and self-reproduction.

Laboratory tests have shown that when cancer cells use certain antimetabolites, cell repairs are faulty and the cells either fail to grow and multiply or they die.

Synthesis of hormonal substances constitutes another promising avenue of cancer research. Both male and female sex hormones hinder the growth of cancer cells by changing the hormone environment which the cells need to continue reproducing.

The chemicals to be synthesized by the six research organizations will be tested against three types of animal tumors. Any of the hormonal substances that show promise will be used in clinical studies which hospitals throughout the country are conducting in cooperation with the National Cancer Institute, Public Health Service.

Stanford Research Institute, Menlo Park, Calif.; Southern Research Institute, Birmingham, Ala.; Medical College of Virginia, Richmond; and Monadnock Research Institute, Inc., Antrim, N. H., will prepare various kinds of antimetabolites for evaluation as anticancer drugs. The Upjohn Co., Kalamazoo, Mich., and the University of Chicago will produce new hormonal substances in quantities sufficient for laboratory studies and clinical trials.

The six contracts involve an expenditure of approximately \$793,000 and will be administered by the NCI Cancer Chemotherapy National Service Center.

Communitywide Pregnancy Reporting in Kauai, Hawaii

FERN E. FRENCH, M.A., LOUISA P. HOWE, Ph.D., JESSIE M. BIERMAN, M.D., ANGIE CONNOR, M.D.,
and DOROTHY H. KEMP, M.D.

A STUDY envisioned in 1953 by Yerushalmy and Bierman starts not with the birth, or the fetal death, but rather with the pregnant woman from the time she becomes aware that she is pregnant (1). Such a longitudinal study entails observation over a period of time of all women in a community who are known to be pregnant. Fetal deaths can therefore be studied not as isolated instances but as part of all the pregnancies in the group. The study on the island of Kauai, Territory of Hawaii, was planned along these lines.

In 1952, the Department of Health, Territory

Miss French is completing work for a doctorate in public health at the University of California School of Public Health, Berkeley. Dr. Howe, resident research director of the Kauai Pregnancy Study, and Dr. Bierman are respectively associate research sociologist and professor of maternal and child health at the same school. Dr. Connor is chief of the bureau of maternal and child health and crippled children's services and Dr. Kemp is director of hospital and medical care, Territory of Hawaii Department of Health, Honolulu.

This is the second report in a series entitled "Longitudinal Studies of Pregnancy on the Island of Kauai, T. H.," financed by the Children's Bureau and conducted jointly by the School of Public Health of the University of California and the Territorial Health Department. This paper was presented in basically the same form during sessions of the 84th annual meeting of the American Public Health Association, Atlantic City, N. J., November 12, 1956.

of Hawaii, and the University of California School of Public Health joined efforts in the countrywide Kauai project, designed to study the outcome of all pregnancies in the community and to learn as much as possible about the factors associated with that outcome. The basic methodology involves periodic investigations made from early in pregnancy through termination in live birth or fetal death and continuing with surviving infants for at least a year.

Thus, unfavorable outcomes can be studied not as isolated instances but as part of all the pregnancies in the group. By following each pregnancy throughout its course and the infant for a period of time, it is possible to study physical and mental abnormalities related to prenatal or natal influences, as well as the social and economic factors involved.

An initial phase of the study used material obtained through a census carried out in 1953 to evaluate the usefulness and limitations of retrospective studies of pregnancy. Retrospective data gathered in this way, shown to be reliable for women under 50 years of age, have provided refined knowledge concerning familial tendency to three components of pregnancy loss: early fetal, late fetal and neonatal, and postneonatal fatalities (2). The second phase had the objective of determining the feasibility of communitywide pregnancy reporting with the size and type of staff and organization used in the study. The collection of adequate material would result in meaningful rates of fetal death, by period of gestation. At the end of the longitudinal study in 1958,

reports will be made on these fetal loss rates and on any associations between factors in the environment of the fetus and newborn and the outcome of pregnancy.

We present here the setting of the study, our experience thus far in communitywide reporting of pregnancies, and data accumulated during the 2½ years ending June 1956. It is hoped that this part of the study, which is comprehensive rather than intensive, will answer a few questions and produce clues for other research by more intensive or perhaps different means.

Setting of the Study

The island of Kauai lies at the northwest end of the Hawaiian chain, some 100 miles from Honolulu. Although three-fourths of the 30,000 inhabitants were born in Hawaii, the population is ethnically variegated. The population pattern shows Japanese (44 percent), Filipino (25 percent), Caucasian (14 percent), part-Hawaiian (11 percent), and a sprinkling of Chinese, Koreans, and Hawaiians. The people live in small towns and plantation camps that are scattered around the shoreline, while the mountainous and often rainy central part of the island is mostly uninhabited.

Agriculture is the principal "industry," the skills it requires increasingly approaching those of a large-scale industrial enterprise. Sugar cultivation goes on all year around, while pineapple harvesting and processing reach a peak in the summer, when a large number of women are employed in the canneries. Rates of pay are comparatively high in these two fields, but employment opportunities are distinctly limited, and other jobs pay poorly. The cost of living is high except for clothes and housing, of which not much is required because of consistently mild weather.

Since 1950 the size of the population has remained fairly constant, but the emigration of many of each year's high school graduates has left a disproportionate number of children and of older men, the latter mostly Filipinos brought in to work on the plantations. In 1950 nearly half of Kauai's dwellings were plantation houses, but since then there has been a notable increase in private home building.

Running water is practically universal, and only a few small districts lack electricity.

Excellent provision is made for health and medical care. There are 13 physicians on the island, 7 associated with the plantations and 2 serving as government physicians. Virtually all plantation employees and their families are enrolled in plantation medical care and hospitalization plans, and the Hawaii Medical Service Association, patterned after the Blue Shield-Blue Cross organization, currently has a Kauai membership of more than 5,000.

Hawaii's health department, one of the oldest in the United States, has had a notable record of achievement in the face of extraordinary problems. For example, it is said that none of the babies born in 1848 survived. Thirty years ago Hawaii's infant mortality rate far exceeded that of continental United States; now it is one of the lowest in the country, with 21 infant deaths per 1,000 live births in 1955. Kauai's rate was a little lower than that of the Territory as a whole.

The search for a place where a community-wide survey of fetal waste and a study of reproductive pathology could be carried out with some hope of success led to the selection of Kauai. The population is relatively stable; people live close to one another and are concerned with each other's welfare; babies are highly prized, and virtually all of them are born in hospitals. A high standard of medical care is maintained and is available to all, and excellent cooperation with health programs has been achieved in the past. It seemed likely, therefore, that such a research project might be given widespread cooperation by the physicians and by the population as a whole.

The Census

After a trial run in the summer of 1952, the first phase of the study got under way in February 1953. Six interviewers resident in Hawaii, 5 nurses and 1 social worker, set about obtaining a census. They listed the occupants of each house and recorded household information and brief personal data, including a reproductive history of all women 12 years of age or older. All apparent prospects were asked if they were then pregnant; if so, the date of the

reported last menstrual period was recorded. A pregnancy report card with a postage-free envelope was left with each woman, and she was requested to mail it to the health department as soon as she believed she was pregnant.

Local physicians were asked to submit each month a list of the mothers who had come to them for prenatal care. During later months, the physicians were supplied with special forms serving, among other purposes, as a source of pregnancy reports to the study. These were used by some physicians.

By September 1953, the enumeration was finished and data necessary for the retrospective phase of the study were at hand. Since then an attempt has been made to obtain similar information on new residents and to record the departure of persons who had been enumerated in the original census.

Campaign for Early Reports

In this study the earliest possible reports of pregnancy are those made by women after their first missed menstrual period. A drive for such early reports of pregnancy began in October 1953. In this same month, 2 public health nurses were added to the regular staff of the health department, regular reports of new pregnancies began to come in from some of the physicians, and newspaper articles about the study appeared in the weekly paper. A series of mother and baby care classes was planned by the health department, and nurses went from door to door asking mothers if they or their friends or neighbors would be interested in such classes—and if they were pregnant. Visits were made to newly wed couples, and talks were given to women's groups and church gatherings.

In the spring of 1954, an all-out drive to publicize the study got under way. Three local community organizers visited women and talked to small groups in various parts of the island, and a reporter's services were engaged for help with newspaper releases. Leaders in the community were brought together for a meeting at which the study was explained, and letters were mailed to all prospectively pregnant women, urging them to see their physicians early and to return an enclosed pregnancy re-

port card when they became pregnant. At meetings of the county medical society, the continued help of the physicians was solicited. As a crowning touch, milk bottles delivered around the island one day were bedecked with a printed message urging mothers to cooperate with the pregnancy study. As a result of these efforts more reports came to the study in 1 month than had ever been received before.

The job of finding new pregnancies continued with radio talks, speakers for various groups, slides shown in the theaters, posters, and mimeographed throwaways. In August 1954 and in January 1955, letters were sent to the pregnancy prospect list, thanking them for their past cooperation and enclosing a report card and envelope once again. In early 1955, the resident research director arrived, and during the next 6 months there was a gradual crescendo of activity. Starting in September, the health department laboratory, from which prenatal serology was ordered by the physicians, became an additional source of reports for pregnancies known to the physicians but not yet reported to the study. The next letter sent to the mothers at the end of 1955 took the form of a calendar with a report card. The campaign for early reporting continued until the end of 1956, when the number of pregnancies for followup was considered adequate.

Periodic Interviewing

Simultaneous with the drive for early reporting was the periodic interviewing of all reported pregnant women during their pregnancy. This activity began in May of 1954. Women identified early were interviewed three times during pregnancy; others twice or only once.

For this part of the study, 2 full-time and 4 part-time interviewers were added to the staff since the load was too heavy for the health department nurses to carry in addition to their regular duties. The project also had the assistance of two office clerks.

In early 1956, the first group of babies born to mothers who had been interviewed during their pregnancy were given pediatric and psychological examinations, procedures heartily welcomed by the mothers. Periodic inter-

viewing is scheduled for completion at the end of 1958.

Resulting Pregnancy Reports

Although some reports of pregnancy were received during the time the population was being enumerated, there was no attempt to obtain early reports until after the census. Since this paper deals with what was done to obtain reports early in pregnancy, analysis is limited to pregnancies with reported last menstrual period (LMP), beginning in 1954. LMP indicates the beginning of the last menstrual period. Weeks of gestation refers to weeks since LMP. Although the date of conception is usually fixed 10 to 14 days after the beginning of the last menstruation (3), conception is used synonymously with LMP here.

In addition to equalizing monthly periods, the lunar month, or 4-week period, has other advantages in keeping track of the week and lunar month of occurrence of many events involved in this kind of study. The first 7-day period in 1953 was called the first week and each succeeding week was given its appropriate number. As a result, intervals between various reports are determined easily. For example, if a first report of pregnancy was made on May 5, 1955, the 70th week, and the reported LMP was December 16, 1954, the 50th week, the interval from LMP to first report was 20 weeks. Groups of 4-week periods were designated as lunar month 1 through 13 for each year. This was particularly useful in comparing lunar months from LMP to first report with lunar months from LMP to first visit to physician or to termination of pregnancy.

Since each report of pregnancy was related back to the lunar month of reported LMP, for any particular month, after 40 weeks or so have elapsed, we accumulate the total cohort with reported LMP in that month. Some are reported soon after the LMP and some are not known until several months later; in fact, full-term pregnancies missed until delivery are not added to the cohort until approximately 10 lunar months after LMP. This procedure means a timelag, of course; cohorts for the first months of 1956 had not been followed completely by the cutoff date of June 30, and, for this reason,

figures 1 and 2 are carried through 1955 only. Cohorts with LMP in late 1955 may be slightly increased with very late reports coming in after June 30, 1956.

Such an allocation has definite advantages in this type of study. During each month there are a certain number of early pregnancies which are available for reporting. By looking at the total cohort, the percentage which was reported, for example, under 12 or 16 weeks' gestation can be determined for each month and results evaluated. After some experience in a community under study, the seasonal pattern of monthly cohorts and the percentage of early reports can be estimated without waiting for the total cohort to accumulate.

The success of the drive for early reporting in the late spring of 1954 and the drop in reports during pineapple-canning season each summer are particularly evident in figure 1. The solid line in this figure indicates the result of allocating each report to the month of reported LMP. As would be expected, fluctuations are less extreme than for reports by month received. With only 2 years for study, generalizations with regard to seasonal variation are not warranted. However, winter and spring months show a somewhat larger number of conceptions than do the summer months.

In table 1 and figure 2 we observe that about 40 percent of all first reports were for pregnancies with gestation period under 12 weeks and 75 percent under 20 weeks, while 90 percent were for those under 28 weeks. The percentage

Figure 1. Month pregnancy report received by study and month of LMP, 1954 and 1955.

Figure 2. Percentage of monthly cohorts of conceptions reported to study by weeks, since LMP, 1954 and 1955.

of reports under 20 weeks was about the same for the 2 years, but the yield of earlier reports was not so large in the second year.

Source of Reports

Notification of many pregnancies were received from more than one of the following sources: the mother, the physician or his records, interviewer's activities, reports of laboratory serology tests, or social agencies. First reports are analyzed here in order to eliminate duplication.

Although most women presumably knew of

the study and had pregnancy report forms available through periodic mailings and therefore could have reported their first missed menstrual period in the 4-7-week period of gestation, only about 20 percent of first reports came directly from them. In spite of publicity that unceasingly stressed early reporting, some mothers were surprised that the study should want to know about them before they were absolutely sure they were pregnant. Indeed, it may be that the study's success in gaining acceptance by the community militated against early reporting by the mothers themselves. Some, when asked why they didn't notify the study immediately after they realized they were pregnant, answered that they knew the interviewer would be around sooner or later anyhow, so what was the need?

However, first reports sent in by mothers themselves were by far the earliest: more than 20 percent were for pregnancies under 8 weeks' gestation compared with 14.4 percent from study interviewers and 5.9 percent from physicians' records (table 2). Almost 90 percent of first reports from mothers were made before the 20th week compared with about 80 percent for interviewers and 70 percent for physicians' records.

¹ Includes reports from health department nurses and 11 reports from social agencies.

² Includes reports from prenatal serology requests and those obtained by interviewers from doctor's records.

LMP=Last menstrual period.

NOTE: Limited to the 1,745 reports made prior to termination of pregnancy.

As it turned out, the largest number of first reports came from the office records of the physicians; these, however, were for more advanced pregnancies, on the average, than reports from other sources. Some physicians or their nurses sent in reports directly; others, however, preferred to have a member of the study staff copy the required information from

their office records. Some pregnancies were missed altogether, and others did not come to our attention until some time after the first prenatal visit to the physician. Beginning in 1955, some pregnancies which were known to physicians but not yet reported were learned about through requests for prenatal serology. Another large group is credited to the initiative of the health department nurses and the study interviewers. For all first reports received prior to termination of pregnancy, the yield of these various sources was about 50 percent from physicians' records and prenatal serology requests, about 30 percent from interviewers, and 20 percent from mothers.

Physicians' Records

Although 50 percent of first reports had their source in physicians' records, the remaining 50 percent were not completely unknown to the physicians. In fact, the study's records show that only 6 percent of all reported pregnancies were without prenatal visits. There are, undoubtedly, some incompleteness and some inaccuracies in the study's records of first prenatal visits to physicians. For example, inconsistencies sometimes appear between the date of the first prenatal visit given on the physician's report form or in his records, and the date reported by women in their interviews. The latter date is sometimes earlier in pregnancy—some physicians probably record as the first

Table 3. Reported pregnancies by weeks from LMP to first recorded prenatal visit to doctor, and by weeks from LMP to first report to study, LMP January 1954-June 1956

LMP=Last menstrual period.

visit the first which is made after the pregnancy is reasonably well confirmed. In this analysis, the earliest visit in the prenatal period is used.

The fact that all but a small percentage were known to physicians prior to delivery points up the potential value of their records as an exclusive source of reports. However, certain questions arise: Were more reported pregnancies unknown to the physicians than to the study? How early in pregnancy were the pregnancies known to the physicians as compared with total reports to the study?

Six percent, or 114 pregnancies, were not reported to the study until a fetal death or live birth occurred, and, by coincidence, the same number, 114, had no recorded prenatal visit to a physician; 4 percent, or 71, were known only to the study and another 4 percent only to the physicians; and 2 percent, or 43, were unknown to both during the prenatal period.

The percentage of total reports known to the physicians in each lunar month of gestation is almost the same as the percentage known to the study (table 3). Close to 50 percent were known to each in the same lunar month. Of the 71 known exclusively by the physicians, 27 percent had no prenatal visit until 20 weeks or more gestation; of the 71 known only to the study, only 10 percent were learned about that late. An analysis of reports by single weeks from reported LMP indicates that for the first 6 weeks of gestation, reports to the study were, on the average, about 1 week earlier than those to the physicians; for the 7th through the 13th weeks there was no difference; for reports coming to the study after the 13th week, prenatal visits to physicians averaged about 1 week earlier.

Comments

Although the longitudinal method used here has definite advantages over the retrospective approach and over studying isolated aspects of the total problem, it presents some difficulties. In a community the size of Kauai with some 5,700 women 15 to 45 years of age, 3 years are necessary to identify about 2,000 pregnant women. Arousing community interest to the high pitch apparently necessary for early reporting, primarily by the women themselves, is obviously a difficult task; and maintaining

such interest over several years is even harder. However, in a community three times the size of Kauai, the early reporting period could probably be cut to 1 year. A shorter time span would certainly be an advantage, although finding a relatively stable and closely knit community of such size is not easy.

As has been pointed out, the earliest possible reports of pregnancy are those made by women after their first missed menstrual period. Although we did not consider it feasible in this setting, it would have been advantageous to have had confirmation of early reports through the provision of pregnancy tests. Furthermore, it is possible that the offering of such tests might stimulate very early reporting and add knowledge about pregnancy wastage during the earliest weeks after conception.

While the analysis of physicians' records as a potential source of pregnancy reports indicates that pregnancies, on the average, were known to physicians on Kauai almost as early in pregnancy as they were known to the study, it is necessary to bear in mind that in many communities, fewer than 94 percent of the pregnant women receive prenatal care. Our findings suggest that among the preliminaries for such a study is an investigation of the extent of prenatal care in the community and how early the care is sought. The custom of the women as well as physicians' policies regarding encouraging or discouraging early prenatal care will be important factors. Of course, the most critical point is the real assurance that all pregnancies, including those that are not yet confirmed, would be made known to the investigators without delay.

Summary

Besides the objective of utilizing data collected at a special census to evaluate the usefulness of retrospective studies of pregnancy, the principal aims of the longitudinal part of the study were to investigate the feasibility of communitywide reporting of pregnancies, to determine fetal loss rates by period of gestation, and to study associations between factors in the mother and the outcome of pregnancy.

A census of the 30,000 inhabitants of the island of Kauai was taken in 1953. The pres-

ent progress report on communitywide reporting of pregnancies deals with the identification, as early as possible after the first missed menstrual period of all women who became pregnant from the beginning of 1954. Periodic interviews of all such women identified and examinations of their babies began in the middle of 1954 and are still continuing.

The great variety of methods used to obtain early reporting of pregnancies included interviewing by regular public health nurses of the health department and by study staff, activities of community organizers, talks to community groups, newspaper articles, radio programs, letters to prospective mothers, and posters.

All reports of pregnancy are related to the month of reported last menstrual period, thereby allowing an analysis by monthly cohorts of conception. About 40 percent of all pregnancies were reported before the 12th week of gestation, 75 percent before the 20th week, and 90 percent before the 28th week.

First reports of pregnancies came directly from mothers in 20 percent of the cases, 30 percent came from interviewers, and 50 percent from physicians' records. Reports were earliest for those who reported least: 60 percent of first reports from mothers were under 12 weeks, 50 percent of the interviewers' reports were in this period, and 35 percent of those from physicians' records.

Although physicians' records yielded only 50 percent of first reports, 94 percent of the pregnant women on Kauai made at least one pre-

natal visit. A comparison between the time when physicians learned of the pregnancies and the time when first reports reached the study shows that physicians knew of the pregnancies almost as early as the study. Some 6 percent were known only to the study (mainly very early pregnancies resulting in early fetal deaths) and another 6 percent were known only to the physicians; 2 percent were unknown to both groups until after termination.

Creating and maintaining interest sufficient to get adequate reporting by the women themselves is an undertaking of no small magnitude. However, if a relatively stable population of larger size than Kauai could be found, the same number of pregnancies could be identified for followup in a shorter period, and community interest would not have to be maintained for such a long period of time.

Reorganization in Michigan School of Public Health

The University of Michigan School of Public Health has set up a new department of industrial health and abolished the department of tropical diseases. This action was taken November 22, 1957. Personnel from the department of tropical diseases have been transferred to the department of epidemiology.

The change reflects a shift in emphasis in epidemiology since establishment of the school in 1941. Tropical diseases were of paramount importance then because of World War II. Now, industrial health has come to the fore with the advent of new plastics, pesticides, and other chemical products, and the interest in radiological health, air pollution, and other aspects of the industrial environment.

The Clinical Pathologist

RESEARCH

Selections from an address delivered by Harold L. Stewart, M.D., at the Joint Annual Meeting of the American Society of Clinical Pathologists and the College of American Pathologists, on October 3, 1957, in New Orleans.

PATHOLOGY may be defined as the study of disease, not merely the study of body fluids and of abnormal morphology. The pursuit of pathology, therefore, includes research and investigation. The clinical pathologist throughout his entire career in a hospital laboratory is asked to advise on and to participate in research problems, and to interpret the re-

sults of research done by others. During his board training the resident pathologist needs to familiarize himself with the methods of experimentation as well as with the broad principles of pathology. How can the clinical pathologist evaluate the results of research by others if he himself has had no instruction in research methods and no actual training or experience in

The Ward Burdick award for 1957, given annually for outstanding service in pathology, has been presented to Dr. Harold L. Stewart, chief of pathology, National Cancer Institute, and chief of the Pathologic Anatomy Branch, Clinical Center, National Institutes of Health, Public Health Service. The presentation was made October 1, 1957, at the Joint Annual Meeting of the American Society of Clinical Pathologists and the College of American Pathologists in New Orleans.

Dr. Stewart, an authority on cancer of the gas-

trointestinal tract, has held office in medical societies including the International Academy of Pathology, the American Society for Experimental Pathology, and the Maryland and Washington, D. C., Societies of Pathologists. He has also been a delegate to a number of international cancer conferences.

The Ward Burdick award is given in honor of the Denver pathologist who founded the American Society of Clinical Pathologists. Dr. Burdick, who died in 1928, was noted for his medical organization work.

the field? To expect this is to expect a man to be a successful clergyman without having studied theology.

THE PATHOLOGIST has independently led the way to many important discoveries. Witness the history of our knowledge of the function of the pituitary gland. It was Pierre Marie who, in 1896, discovered the role of the anterior lobe of this gland in acromegaly, and it was Benda who found growth to be related to the alpha cells. But this important finding was left for the biochemist and endocrinologist to exploit, chiefly because the pathologist was not skilled in other techniques. Pathology, it has been said, depends upon tools of other disciplines for its research. The pathologist of the recent past leaned heavily on bacteriology and immunology for problems in experimental pathology. Today, the experimental pathologist utilizes chemistry and physics in the study of molecular diseases and he will need to learn many techniques to equip himself to take advantage of the wealth of opportunities that he has for research.

It is safe to predict that in time all the lesions of human beings will have been studied by electron microscopy. Just as our knowledge of lesions first studied by the naked eye was enormously increased by study with the light microscope, so will our present knowledge of the histopathology of these lesions be expanded by the resolving powers of the electron microscope. No one is better qualified than the clinical pathologist to study pathological lesions by electron microscopy. He is not just a microscopist seeing particles whose significance he is unable to interpret but is one widely familiar with the morphology and biology of disease.

The "mitochondria" revealed by the electron microscope and the mitochondria isolated by the biochemist in differential centrifugation, which are hailed as something new and strange, were discovered in Leipzig by the pathologist Richard Altmann in 1890 and named in 1898 by the pathologist Benda, who studied them in pathological tissue. The pathologists gave this discovery of mitochondria at once to the biochemist and the cytologist, who believed them

to possess and probably to produce most of the cytochrome oxidase and other respiratory enzymes of the cell. Little is known of these organoids in pathological tissue and nothing of their behavior in human tissue. The pathologist should now return to this important field after more than 50 years of neglect.

THE DISCOVERIES that cancer can be induced by X-rays, by tars, and by aromatic polycyclic hydrocarbons led to a great deal of work on carcinogenesis which during the 1940's and thereafter has waned. Today too few pathologists are trained in experimental carcinogenesis. The techniques are not difficult to master. The clinical pathologist already possesses the necessary basic knowledge, including the procedure for a careful autopsy. Almost the only other things he needs to know are the design of the experiments and the methods of preparation of the known or suspected carcinogens for their administration by different routes. . . .

THE FOOD on the American table today in a well-balanced diet of acceptable form may contain many synthetic additives. Some may be toxic and some even carcinogenic for laboratory animals, while other food additives utilized for years past have never been tested adequately for chronic toxicity and cancer-inducing activity. New food additives are being introduced at a rate that precludes careful toxicological testing unless the number of investigators in the field of carcinogenesis be considerably expanded. There is pressing need for experimental research in this field.

THE CHEMIST, the biologist, or the physicist who does research may know his own subject thoroughly, but usually knows nothing whatever about pathology. The pathologist, on the other hand, well trained in anatomical pathology and laboratory medicine, also knows a good deal about chemistry, biology, and physics. Some pathologists have majored in one or another of these subjects, and others hold the degrees of master or doctor of philosophy. This makes the pathologist an ideal collaborator

in research problems, the primary scope of which lies outside the field of pathology.

A number of research problems, the basis of which lies primarily in disciplines other than pathology, still require pathology for their interpretation and solution. Too often, the pathological material in such experiments is discarded without examination. Not long ago, I read the report of a long-term toxicological experiment involving more than 500 rats. The statement was made that the rats were necropsied and no tumors were found in either the control or the experimental animals. It would be virtually impossible not to find many tumors in 500 rats, 20 or more months of age, of any special strain or breed or randomly selected market rats. Of course, a tumor does not exist for the investigator who does not have the training to detect a tumor at necropsy. It is important, therefore, for pathologists to collaborate with experimentalists trained in other disciplines so that the pathological lesions are properly recognized and recorded.

WHAT are the characteristics of a research man? No prevailing characteristic to my knowledge marks a potential investigator, unless it be the possession of an innate drive to explore a new idea even against advice. Certainly, there is no average investigator. Research has been defined in part as finding things without being told. The investigator is able to correlate seemingly unrelated facts. He knows what constitutes proof. Young or old, he must be keen enough to observe his results no matter in what direction his experiment leads and to turn his mistakes to good purpose. The research worker himself is a worthy subject for research, and some day some enterprising student of psychology may determine and record the recipe of his composition.

The greatest caution should be exercised to avoid the discouragement of a young resident who proposes an experiment. The experiment may appear inconsequential and often wholly impractical, but I have found that it is unwise to ridicule any plan for an experiment. It happens ever so often that one of these seemingly inconsequential or impractical experiments leads to results of great importance. It was the

usefulness of seemingly useless research knowledge that led Marconi to develop wireless telegraphy. The most important factors in research are a desire to do an experiment and the impatience to get to work on it. All else is subordinate. A proposed experiment is often condemned because it has been performed previously. One needs only recall that prior to the development of insulin therapy for diabetes by Banting and his associates, other investigators had studied the effects of ligation of the ducts of the pancreas. Yet it was Banting who finally extracted the active factor from the islets of Langerhans by using modifications no one had carried out successfully before. It is clear that even though an experiment may have been performed previously something new may be found upon repeating it.

The beginner in research is apprehensive lest he err in his first experiment. Inertia retards many aspiring scientists from taking their first steps in the field of research. One has to get on with the work and realize that mistakes are inevitable. They can, however, often be turned to profit and may lead to the solution not necessarily of the problem under investigation, but rather of another entirely different and often more important one. It does not matter much whether the resident discovers anything new or publishable. The experience gained will be sufficient reward. Those who direct programs of residency training have a responsibility to see to it that these fine minds are given the opportunity to bring their ideas and talents to bear on experimental problems. Finally, the young investigator should be warned that for a large part of the time he works in research he will be doing the hardest and most uninteresting kinds of work that may involve cleaning animal cages, washing glassware, and cleaning up after necropsies. He needs encouragement and consolation together with all the help that can be given him to lessen the onerous duties that constitute so much of research.

THE TRAINING of a pathologist in the modern aspects of service work in clinical pathology has reached a peak in the United States that is unsurpassed elsewhere in the world. However, his reading should not be

limited to factual textbook material. He should be encouraged to read some of the original speculations of the great thinkers in pathology and research. How many residents are advised to read Nicholson's provocative essays on the formation of tumors, or Rokitan-sky on the humoral theory of disease, or Virchow on cellular pathology? or indeed such classics as the autobiography of Sir Ronald Ross? . . . The training of a pathologist in tumor pathology emphasizes accurate diagnosis of the biopsy specimen—almost never speculation as to the possible causes of tumors.

The resident training program should provide (a) more time to think and philosophize; (b) more instruction in the design and execution of experiments and the interpretation and application of the results; (c) recommendations for reading original contributions to research; and (d) access to library facilities that are adequate for the needs of a research worker.

HOW does the admissions committee choose or reject a candidate for medicine, and what is the impact of his choice on research in pathology? It is, I am told, the aim of many admis-

sions committees to select applicants on the basis of high grades in college and the possession of certain qualities . . . that somehow or other indicate that the selected individuals will become good practitioners of medicine. So far as I know, no admissions committee deliberately selects students for medical school who possess the qualities needed for research. Consider the influence on the admissions committee of an answer to a question that the candidate for medical school might be asked. The question may be: "Did you go to the football game last Saturday?" Suppose the reply is "I spent the afternoon in the library reading some early editions of Machiavelli's *The Prince*," or "I spent the afternoon in a cool, quiet saloon scheming to eliminate some stupid premedical courses." Are these the kinds of answers calculated to get oneself admitted to medical school? And yet one must admit these answers reflect both honesty and originality, two excellent qualities for an investigator.

Dr. Stewart's paper will appear in full in the American Journal of Clinical Pathology.

Health Research Facilities Grants

Expansion of the Nation's health research facilities by at least \$120 million is under way as a result of grants awarded by the Public Health Service during the first 2 years of its 3-year grant program.

Financed by an appropriation of \$30 million authorized for each year, the grants are allotted for construction and improvement of facilities devoted to research in the basic science areas on such diseases as cancer, heart disease, and mental illness. An amount equivalent to the grant, or more, is supplied by the participating institution.

Approval of 43 new grants totaling \$3,698,452, in October 1957, completed allocation of the \$60 million appropriated for fiscal years 1957 and 1958. Benefited in the latest action were 39 institutions in 22 States, the District of Columbia, and Hawaii.

Under the new program, grants are approved by the Surgeon General on the recommendation of the National Advisory Council on Health Research Facilities. A total of 251 grants have been made since the program's inception in June 1956.

Clinical, X-ray, and Serologic Changes With Histoplasma Infection

NORMAN W. ANDERSON, M.D., IRENE L. DOTO, M.A., and
MICHAEL L. FURCOLOW, M.D.

ALTHOUGH considerable information about histoplasmosis has been accumulated since this fungus infection was first described in 1906, much still needs to be learned about the frequency and severity of the disease accompanying primary infection. Following the classic work of Smith and his colleagues on *Coccidioides* infection in personnel of the U. S. Army (1), it was decided that such personnel, with their available medical care and complete records, would be an ideal group for a study of histoplasmosis. Consequently, in 1953 a study was initiated at Fort Leavenworth, Kans., by the U. S. Army Hospital on the post and the Public Health Service. Children of Army personnel participated.

The study was undertaken to determine the spectrum of illness accompanying *Histoplasma* infection. This was accomplished by observation of the clinical, X-ray, and serologic changes which accompanied conversion of the skin test from negative to positive. Its basic plan was to find a large number of children

with a negative reaction to the histoplasmin skin test, observe these children over a period of time, and retest them to determine the infection, or conversion, rate. Clinical, X-ray, and serologic changes could thus be observed in a group who became infected and in a much larger group who did not and who therefore would serve as controls. Other interesting epidemiological information concerning infection was also collected.

Material and Method

Fort Leavenworth, in northeastern Kansas about 30 miles from Kansas City, is the seat of the Command and General Staff College of the Army. The vast majority of the men stationed at this post are officer students of the school, arriving in August each year and departing the following June. These officers and their families have already had several years of Army life before coming to the post, including residence in all parts of the country and overseas. The children of these families formed the bulk of the children included in this study. Most of the remainder, but less than 10 percent of the total population tested, were children of the permanent personnel of the post living in the city of Leavenworth.

A preschool physical examination of all children is conducted routinely by the Army medical staff each August and September when the new families arrive on the post. In May of each year a smaller roundup is held for children who have arrived on the post or in the area later in the school year. These two examina-

Colonel Anderson is commanding officer of the U. S. Army Hospital, Fort Leavenworth, Kans. Miss Doto is statistician, and Dr. Furcolow chief, Kansas City Field Station, Communicable Disease Center, Public Health Service, University of Kansas Medical Center.

Col. R. M. Patterson and Lt. Col. Francis W. Lanard assisted in the supervision of the study; Capt. Sumner Hoffman and 1st Lt. Sheldon Kessler in the testing, and Maj. R. V. McAllister in the X-ray interpretation. David Sachs and Peter Ney assisted in the statistical analysis.

tion periods provided an opportunity for at least two tests of a large number of children, with a suitable observation period between.

For the histoplasmosis study, September 1953 through May 1955, skin tests with histoplasmin were given along with the routine tuberculin and Schick tests. All children present at the examination received the skin test. They ranged in age from 5 through 18 years.

In the fall of 1953 approximately 1,500 children were skin tested for histoplasmosis, and the following May those whose initial tests were negative were retested. Also in May, 50 more children were added to the study. In the fall of 1954 the 600 histoplasmin negative children who were still on the post from the previous year were retested, and 1,300 new arrivals received their first test. Those retested included the negatives among the 50 added in May, who were being retested for the first time, and continuously negative children, who were being retested a second time. The histoplasmin negatives among these 1,900 children were retested in May 1955. A total of 2,872 children were included in the study.

The histoplasmin used was lot HKC-5 diluted 2:1,000. This potency is equivalent to that of standard histoplasmin. The tests were all given intradermally in the right arm, and readings were made at 48 hours with measurement of the erythema and induration. An induration of 5 mm. or more at the 48-hour reading was considered a positive reaction. Children whose skin tests changed from negative to positive during the interval between the two examinations were converters. Those whose tests remained negative and those with positive reactions on the first test served as controls.

At the time of the two fall skin tests, blood was obtained for a serologic test on each alternate positive reactor to histoplasmin. When the negative reactors were retested, either in the spring or in the fall, blood specimens were obtained from all the children whose skin tests had changed from negative to positive and on the preceding and succeeding child in the examination line. The latter procedure provided controls, children whose skin tests remained negative, for the serologic testing.

Table 1. Percentage of children positive to histoplasmin on initial test, according to age, Fort Leavenworth, Kans., 1953

Age (years)	Number tested	Number positive	Percent positive
3-4-----	263	5	1.9
5-6-----	470	21	4.5
7-8-----	314	17	5.4
9-10-----	271	21	7.7
11-12-----	136	21	15.4
13-18-----	86	17	19.8
Total-----	1,540	102	6.6

Serologic tests were performed by Dr. Joseph Schubert of the Communicable Disease Center, Public Health Service, Chamblee, Ga., and by Dr. Samuel Salvin of the Rocky Mountain Laboratory, Public Health Service, Hamilton, Mont. Dr. Salvin performed a precipitin test using purified histoplasmin as the antigen and a complement fixation test using whole yeast phase organisms as the antigen. Dr. Schubert performed a complement fixation test using histoplasmin as the antigen. These tests were done without knowledge of the skin test status of the individual.

Depending on the size of the child, either an 11- by 14-inch or 14- by 17-inch chest X-ray was obtained for each at the time of the initial histoplasmin skin test. At the time of the retesting similar X-rays were taken of all children whose skin tests had changed from negative to positive and on some of the children selected for controls. At the same time second X-rays were taken on the initially positive reactors who had been serologically tested in the previous examination. All X-rays were interpreted by a qualified radiologist as well as by other physicians experienced in the interpretation of chest X-rays.

During the retesting, a questionnaire was given to the parents of each child. It asked about family visits of a day or more off the post, any illnesses which had occurred in the interval between tests, and other pertinent epidemiological factors. To supplement the questionnaire data, clinical records at the outpatient clinic and the post hospital were reviewed for pertinent illnesses during the interval. Illnesses associated with upper respiratory infec-

tion, bronchitis, pneumonia, and gastrointestinal disturbances were considered pertinent and were summarized on the child's record with respect to onset and duration. Clinic records were available for 2,375 of the children. They were not available for the remaining 497, including 2 converters, because of the transfer of the father.

Basic Prevalence and Conversion Rates

In table 1 are shown the age-specific rates for histoplasmin sensitivity determined from tests of 1,540 children in September 1953. The overall prevalence is about 7 percent, with children

11 years and over showing much higher rates (average 17 percent). The percentage positive increases with age even though the geographic background of these children is varied. The prevalence of histoplasmin skin test sensitivity observed for the succeeding periods of study was similar to that for the first.

The age-specific conversion rates, shown in table 2, are based on the number of negatives that were retested at the end of each observation period and the number of children who had converted to a positive reaction during the period. Rates were calculated for the period of observation and then adjusted to a yearly rate. The total yearly rate for the first 8-month period (winter 1953-54) is about twice as high as that for either of the other two periods, and this seems attributable to an excessive rate of conversions among children aged 7-10 years during that particular period. The tendency for increasing rates of conversion with increasing age is apparent during all the periods. The 13- to 18-year-olds exhibit an annual rate of 11 percent compared with 3.6 percent for children aged 12 years or less.

Further analysis of the conversion rates is seen in table 3, which shows the rates of conversion among residents and among nonresidents of the post who returned questionnaires. Nearly all the nonresidents lived in the town of Leavenworth. The conversion rate for 144 nonresidents was 11.6 percent, whereas the rate for 2,101 residents was only 4.2 percent, one-third as high. These figures include all three observation groups. The annual conversion rates for the nonresidents were consistently higher in all 3 periods, running from 9 to 16 percent com-

pared with 2 to 6 percent for the nonresidents. Five of the ten nonresident converters were 11 years old or more, yielding a crude conversion rate of 21 percent compared with 4 percent for residents of the same age. For those under 11 years of age, the crude rate was 4 percent for

the nonresidents as opposed to 2.6 percent for residents.

Changes Accompanying Infection

Table 4 shows the prevalence of different types of illness among all the children for whom clinical records were available, including not only those who became infected (the converters) but those already infected (the positives) and those not infected (the negatives). The illnesses are classified as upper respiratory infection, bronchitis and pneumonia, and gastrointestinal infection.

Sixty-seven percent of the children who were histoplasmin negative had a clinical record of upper respiratory illness, while 58 percent of the converters and 63 percent of the positives reported such illnesses. For bronchitis and

¹ X-rays on 2 converters misfiled and not located.

pneumonia the percentages were 13, 11, and 4, respectively. Thus there was no evidence of a greater frequency of respiratory illnesses among the converters than among either the continuously negative children or those previously infected. It is worth noting, however, that 58 percent of the converters had an upper respiratory illness and that 23 percent, or nearly half of these, had cases lasting 4 days or more.

The results of X-rays taken at the time of the original examination, in September 1953, are given in table 5. Among the children who had negative X-rays, 5 percent were histoplasmin positive. Among those who had lesions, 55 percent were histoplasmin positive, and among those who had calcification, 66 percent were positive to histoplasmin. Thus, frequent association of pulmonary calcification and lesions with positive histoplasmin skin tests is evident. Similar figures were observed for children admitted later to the study.

Table 6 shows the results of X-rays obtained on children who had X-rays both in the initial

Figure 2. W. S. W. M., age 4: Histoplasmin skin and chest X-ray negative in September 1954. In May 1955 histoplasmin skin test positive, 20-mm. induration. Only illnesses were tonsillitis in January 1955 and common cold in March 1955. X-ray taken May 23, 1955, showed pneumonic area in left mid-lung extending out from hilus. Area showed little clearing 3 days later. Serologic tests for histoplasmosis positive May 18, 1955.

Figure 1. R. S. W. M., age 10: Histoplasmin skin test and chest X-ray negative in September 1953. Histoplasmin skin test positive in May 1954. Chest X-ray May 22, 1954, revealed enlarged right hilar lymph node. Still present July 19, 1954. Three common colds from January to April 1954; bronchitis in November 1953. Serologic tests for histoplasmosis positive May 24, 1954.

examination and on a retest, including those who had X-rays taken because of conversion of the skin tests, the negatives chosen as serologic controls, and the initial positives who had received serologic tests. Of 238 children who had more than one X-ray, 147 were negative on both the initial and the retest X-ray. Fourteen had lesions on both films and 68 showed calcification on both films. The most important happening in this phase of the study was the development by 9 children of a lesion during the period between the 2 X-rays. Six of these nine were among 66 converters, and 3 were among 140 children whose skin tests were positive at the initial examination. Thus almost 10 percent of the converters developed a lesion compared with 2 percent of the initially positive reactors. Two of the lesions which developed among the converters are illustrated in figures 1 and 2.

Table 7 shows the results of serologic tests performed on 320 children in the study. Of

¹ 6 converters had no serologic tests.

these, 26, or 8 percent, had positive reactions.

Among the converters 21.0 percent had positive serologic tests, whereas among those remaining histoplasmin negative only 3, or 2.6 percent, had positive tests. Two of the latter three were low titer precipitin tests, a test for which some nonspecificity is known to exist. The remaining test was a minimal positive in the complement fixation test. Five converters had minimal positives in 1 of the 3 serology tests, 2 in the histoplasmin CF test and 3 in the yeast phase CF test. All the other converters yielded a higher response in one or more tests. Among the positive reactors in the first test, 6.9 percent had positive serologic tests.

Table 8 correlates the illness experience and the serologic and X-ray results among the converters. Of the 6 who developed a chest lesion

during observation, 4 had a positive serologic test and 3 had an illness. Among the 60 who did not develop chest lesions, 7 of the 33 who had illness also had a positive serologic test; only 2 of the 22 with no illness had a positive serologic test. Whenever both illness and chest lesions occurred, serologic tests were usually positive. Children not developing lesions did not show as high a prevalence of positive serologic tests as those who did.

Epidemiology

As already noted in table 3 the conversion rate among residents of the post was about one-third that of nonresidents.

Table 9 shows a comparison of the histoplasmin conversion rate between individuals who visited off the post during the observation period and those who did not. A visit off the

post to a farm was apparently a considerable factor in *Histoplasma* infection, doubling the rate of conversion of the skin test. This has been commented on previously (2). Visits to farms, however, do not explain all the infections which occurred since 47 of the 58 converters denied visiting a farm.

Since there was evidence of infection taking place on the post, further efforts were made to locate a possible source. It is a well-known fact that histoplasmosis is often incurred in old houses, belfries, and other places in which pigeons have been roosting. Since pigeons are plentiful in the old buildings at Fort Leavenworth, the relationship between pigeons roosting on the roof of the houses and histoplasmin conversion was considered. As shown in table 10, the histoplasmin conversion rate among those reporting pigeons on their houses

was more than twice that among the others on the post. This difference was most pronounced during the first observation period, the winter of 1953-54, when 10 percent of the children living in houses where pigeons roosted were histoplasmin positive, compared with 3 percent of those not so associated with pigeons.

Annual conversion rates for different areas of the post for the two winter periods are shown in figure 3. The distribution of converters is not at all uniform, area V showing the highest rates each year. These higher rates were not due solely to the concentration of pigeons men-

Figure 3. Annual histoplasmin conversion rates for five residential areas at Fort Leavenworth, 1953-55.

NOTE: Rates are adjusted to cover 12-month period.

tioned earlier because this concentration covered areas III and IV as well as V.

The extraordinary rate of histoplasmin conversion in area V led to additional investigation, which disclosed that 9 of the 12 converters during the first year lived in a large 3-story apartment house, the Beehive, which sheltered more than 50 families. These 9 converters came from a group of 97 children living in this house who were negative at the time of their first test in September 1953. Eight of the nine converters lived on the third floor, yielding a conversion rate of 27 percent for the children on this floor (table 11). The remaining converter lived on the first floor. In contrast, during the second winter observation period, only 4 of the 72 Beehive residents became histoplasmin positive, and only 1 of them lived on the third floor.

On further inquiry into the difference in conversion rates in the Beehive during the two periods, it was found that a sprinkler system had been installed in the attic of the building during the fall and early winter of 1953. The installation necessitated cutting holes for pipes through the attic floor and the ceilings and floors of the rooms below down to the basement. Furthermore, the attic had a number of broken windows, which permitted pigeons to enter and

nest in the attic. Large amounts of pigeon dung were found scattered throughout the attic, and holes had been bored through some of these areas. In addition, at the time the sprinkler system was installed it was necessary to remove a false floor in the attic, an operation which created a tremendous amount of dust and unquestionably stirred up the pigeon excreta which had been deposited on this false floor. Cultures from pigeon nests in the attic obtained a year or so later, however, showed no evidence of *Histoplasma capsulatum*.

Discussion

The frequency of clinical illness among children converting from negative to positive on the histoplasmin skin test resembled superficially that observed in *Coccidioides* infection. The percentage of converters ill with upper respiratory infection, bronchopneumonia, or bronchitis of at least 4 days' duration was 30 percent in this study, compared with 24 percent with clinical illness in Smith's survey in Army camps (1). Sixty percent of those who became infected with *Coccidioides* and 42 percent of those who became infected with *Histoplasma* showed no upper respiratory illness. However, the incidence of illness among converters at Fort Leavenworth differed little from that of the control groups. Whether or not the same situation prevailed in the *Coccidioides* study cannot be determined because no studies on controls were done.

That *Coccidioides* infection is sometimes even less manifest than in Smith's report is indicated by the following quotation from a presentation at the Coccidioidomycosis Conference, Phoenix, Ariz., February 11-13, 1957, by Dr. Paul G. Hugenholtz, formerly chief, Medical Service, Williams Air Force Base, Ariz.: "Forty-four converters to the coccidioidin skin test were observed among approximately 200 skin test negative recruits retested at 3-month intervals. Only 1 of these 44 is a clinically recognized case, and 5 other men had only a 'cold.' Indeed the illness was so vague that I would classify 43 of the 44 as 'inapparent infections'."

The similarity in frequency of illness among the converters and the control groups consisting of previously infected children and those

Table 11. Histoplasmin conversion rates according to floor of apartment house (Beehive), Fort Leavenworth, Kans., 1953-55

Floor	Number negatives retested	Number converters	Percent converters
Winter 1953-54

2d.....	30	0	0
3d.....	30	8	27
Total.....	97	9	9
Winter 1954-55			
1st.....	27	3	11
2d.....	17	0	0
3d.....	28	1	4
Total.....	72	4	6

continuously negative at Fort Leavenworth is probably due to the infrequency of the *Histoplasma* infections (only 68 children among 2,662), compared with the frequency of other causes of illness; only 2.8 percent of the children became infected with *Histoplasma*, but 85 percent showed some type of illness. It may also be that *Histoplasma* infections in children are somewhat milder than infections in older people, which on the whole have been rather severe as seen in reports of epidemics of histoplasmosis. Perhaps dosage may be the important difference. It is important to note that both in the development of chest lesions and in the serologic tests a definite difference could be detected between the infected group and the control group. Certainly there is adequate evidence in the literature to substantiate the potential seriousness of both epidemic and sporadic histoplasmosis. One can only conclude that under the conditions of this study *Histoplasma* infections were not frequent enough or severe enough, or otherwise sufficiently different, so as to be distinguished from the other infections seen in the controls of similar age and with similar exposure.

The study indicates a direct relationship between the incidence of histoplasmin skin test conversions and residence off the post in Leavenworth and nearby Missouri and Kansas towns, visits to farms regardless of location, and association with pigeons. Conversion rates were especially high during the first year of the study among the top-floor residents of one large apartment house, where a sprinkler system was being installed. The remodeling required by installation of this equipment undoubtedly scattered pigeon dung deposited in the attic. The rates of infection were markedly lower the second year of the study, after the remodeling had been completed. Although *H. capsulatum* could not be demonstrated in material collected from the attic at a later date, the epidemiological data definitely point to dissemination of the infection from dry dust and pigeon manure stirred up by the remodeling.

Comparison of the prevalence of histoplasmin sensitivity among these Army children with that of natives of the area is interesting.

A previous study has shown that the rate among the natives is much higher; it is about 47 percent at ages 7-8 years, as compared with about 5 percent for the Army children of these ages. The difference is further brought out in table 3, which shows that nonresidents of the post (most of whom lived in Leavenworth) had a histoplasmin conversion rate three times higher than residents of the post. Also the rates of conversion are higher among the older children than among the younger ones (table 2). This may be associated with the fact that all the children, even those living on the post, attend high school in Leavenworth and are thus exposed to the factors which account for the high local rate.

Summary

Clinical illness, development of chest lesions, and serologic changes accompanying infection with *Histoplasma capsulatum* were studied in children of United States Army personnel stationed at Fort Leavenworth, Kans. Of 2,662 with a negative reaction to the histoplasmin skin test on the first examination, 68 had a positive reaction to a second test 5 to 8 months later. Uninfected children, as well as those previously infected, served as controls for these converters.

Illness accompanying infection did not occur frequently enough to be separated from the routine upper respiratory illnesses occurring among the controls. This lack of definition may have been due to the infrequency of *Histoplasma* infections in these children (only 4 percent per year) in comparison with the frequency of upper respiratory infections (58 percent for the converters and 66 percent for the rest of the children in the study).

Chest lesions, evident on X-rays, developed more frequently among the converters than among the controls. Similarly, serologic tests were more often positive among the converters, and there was a definite relationship of serologic test results to illness and the development of chest lesions.

Epidemiological observations indicate that *Histoplasma* infections among these Army children resulted from several of various potentially infectious factors. These may be listed in the order of importance as living off the post,

visits to farms, living in a house frequented by pigeons, and, finally, living in a house where exposure to pigeon excreta unquestionably occurred.

publications

Public Sewage Treatment Plant Construction, 1956

PHS Publication No. 549. 1957. 15 pages. 15 cents.

Fifth in a series, this report gives the number and amount of contracts awarded for the construction of sewage treatment plants by municipalities in 1956. The awards are broken down by 15 major drainage basins of the United States, by population groups, and by size of contract. Place, type of construction, and cost of each contract are listed in the appendix.

The effects of the Federal grant program under Public Law 660 (84th Cong.) are not reflected since there has not been sufficient time to determine them.

20th Anniversary of the National Cancer Institute—Commemorative Symposium

Journal of the National Cancer Institute, Vol. 19, August 1957. \$2.00

Members of the staff of the National Cancer Institute, Public Health Service, have contributed special articles for this commemorative issue. Beginning with the text of the National Cancer Institute Act of August 5, 1937, they review the

development and accomplishments of cancer research and programs for cancer control.

Present and former members of the National Advisory Cancer Council, present Institute staff, and deceased staff members are listed in the appendix.

A Comprehensive Program for Water Pollution Control for the Meramec River Basin

Water Pollution Series No. 72. PHS Publication No. 553. 1957. 7 pages.

One of a series presenting comprehensive pollution abatement programs developed by the States and adopted by the Surgeon General in accordance with the new Federal Water Pollution Control Act (P. L. 660, 84th Cong.), this publication summarizes the program developed by the Missouri Division of Health and the Public Health Service to control pollution in the Meramec River Drainage Basin (eastern Missouri).

The program provides an objective plan for citizens of the area and city officials and industrial leaders, farmers, fishermen, conservationists, and others. Projects (new plants, replacements, enlargements, additions) required to bring water pollution under control in the Meramec

River Basin are listed. Other recommendations relate to the operation of existing municipal and industrial waste treatment works, provision of adequate sanitary facilities and practices at camps and recreation centers, and control of new and increased sources of pollution.

Barbiturates As Addicting Drugs

PHS Publication No. 545. 1957. Folder. \$2.50 per 100.

Prepared by the National Institute of Mental Health, Public Health Service, this folder points out the dangers of uncontrolled, habitual use of barbiturates. It describes the symptoms of barbiturate intoxication, how experiments have proved that addiction occurs, what kind of treatment is indicated, and why further research is needed.

This section carries announcements of new publications prepared by the Public Health Service and of selected publications prepared by other Federal agencies.

Unless otherwise indicated, publications for which prices are quoted are for sale by the Superintendent of Documents, U. S. Government Printing Office, Washington 25, D. C. Orders should be accompanied by cash, check, or money order and should fully identify the publication. Public Health Service publications which do not carry price quotations, as well as single sample copies of those for which prices are shown, can be obtained without charge from the Public Inquiries Branch, Public Health Service, Washington 25, D. C.

The Public Health Service does not supply publications other than its own.

X-ray Case-Finding Programs in Tuberculosis Control

SINCE the 1940's, mass radiography of the chest has been a fundamental technique in the detection of tuberculosis in this country. In 1956 approximately 70,000 new active cases of tuberculosis were discovered, a substantial portion of the total by this means.

As originally constituted, mass X-ray surveys had communitywide application and were designed to reach from 70 to 80 percent of the adult population within a limited time. The rationale that motivated this method of attack was that most of the unknown active cases in the population would be discovered and eventually isolated, treated, and rehabilitated, and that presymptomatic disease would be discovered at a stage before irreparable lung damage had been done.

The only limitation or selection imposed upon these communitywide survey enterprises, in actual practice, was a minimum age. Persons younger than 15 years of age were usually excluded because of both the difficulty of obtaining satisfactory films and the low yield of cases among children. The working assumption was that tuberculosis was a problem of the general adult population and called for widescale intensified attack.

In the last 15 years the tuberculosis problem has changed radically. There are areas of the country where active tuberculous disease is almost nonexistent. And there are many other areas where tuberculosis continues to be a serious public health and medical problem. There are a number of special groups that carry a heavy burden of tuberculosis and constitute a fertile source of future cases. Thus, tuberculosis continues to be a stubborn problem, and X-ray case finding remains a primary factor in its solution. However, the emphasis has shifted

as the tuberculosis control challenge has changed.

Perceiving the nature of this change, the Public Health Service has been supporting for some time the selective use of mass X-ray survey facilities and has promoted their application in population groups at high risk of infection and disease, such as, hospital admissions, patients and employees in mental hospitals, inmates of correctional institutions, low economic groups, particularly those in slum areas, migrant laborers, alcoholics, and others. Contacts of open cases and persons with symptoms typical of tuberculosis constitute other groups that should receive prime attention in case-finding activities.

In applying the principle of selectivity, the yield of new cases should be a strongly influencing factor in establishing priorities for survey programs. Nevertheless, it is recognized that, within the identifiable types of population groups suitable for X-ray case finding, there are wide ranges in the number and rate of discoverable cases. Therefore, no nationwide priority can be established on the basis of gross categories of population. Necessarily, prior-

This statement, approved by Surgeon General Leroy E. Burney, was prepared with the advice of:

Dr. Russell H. Morgan, Johns Hopkins University Hospital, and special consultant to the Surgeon General on the public health aspects of radiation.

Dr. Ralph Dwork, director of health, Ohio Department of Health.

Dr. Floyd Feldman, medical director, National Tuberculosis Association.

Dr. Joseph Stocklen, tuberculosis control officer, Cleveland and Cuyahoga County Health Department, Ohio.

ities should be determined by the epidemiological demands of the particular local situation. For example, the range of rates of newly discovered cases in correctional institutions indicates that this population group may deserve a very high or a very low priority, depending upon the particular local situation.

Selection of areas of case-finding activity should also be determined by the quantity and quality of available followup, diagnostic and treatment facilities, cost, availability of personnel, and by the community's potentiality for making the maximum utilization of survey findings. When X-ray screening is planned for any group, it is essential that facilities for differential diagnosis be provided so that virtually all clinically significant cases of tuberculosis will promptly come under medical care. Where such facilities are limited, X-ray screening programs should be so restricted as to insure adequate diagnosis and medical care of new cases found.

In low-prevalence groups, tuberculin skin testing is useful as a first step in case finding. X-ray activities could thus be restricted to reactors to tuberculin. As a result, the necessity of screening the whole population would be obviated.

In consequence, the Service proposes that every community evaluate on a continuing basis its tuberculosis problem, its specific needs and its resources, so that X-ray surveys may have maximum effect in terms of number of cases found, the reduction of the reservoir of unknown infectious cases, and, through adequate and enduring followup activities, the breaking of chains of infection.

For many years it has been known that there is a risk of excessive radiation exposure involved in the use of X-ray machines. Current findings in this field that emphasize the significance of relatively low-level radiation exposure now serve to focus attention on the need to maintain and operate X-ray equipment in such a way as to eliminate all unnecessary radiation.

To achieve this purpose, the Public Health Service recommends the following procedures: Systematic inspection should be made of all X-ray case-finding equipment, so that radiation exposure to the population may be reduced as

much as possible. Photofluorographic X-ray equipment should be inspected prior to the beginning of a survey and at frequent intervals thereafter. Of particular importance in this connection are: (a) permanent installation of the proper size cone, so as to limit the field of radiation to the area of the fluoroscopic screen of the photofluorograph; (b) the interposition of a filter of at least $2\frac{1}{2}$ millimeters of aluminum in the useful X-ray beam to eliminate the soft radiation; (c) radiation levels at locations where technical and other personnel are situated and where incoming and outgoing examinees are stationed, consistent with the standards set forth in the National Bureau of Standards Handbooks 59 and 60.

A committee of experts has had under review for some time the problems associated with radiation exposure. It is their considered judgment that the risks inherent in such exposure, although important, are relatively small compared to the very great benefits to be achieved from chest X-ray case-finding programs when conducted within the principles set forth in this document.

Summary

The following, then, are the guiding principles that unify the policy of the Public Health Service as it bears upon tuberculosis X-ray case-finding activities:

1. Mass radiography of the chest, operated under competent auspices, is a fundamental technique in the detection of tuberculosis.

2. Mass X-ray case finding should be applied selectively in groups at high risk of tuberculosis infection and disease.

3. All tuberculosis X-ray survey programs should have the prior approval of the applicable State or local health department.

4. Consideration should be given to the tuberculin test as an initial screening device in low prevalence groups.

5. Every community should evaluate on a continuing basis its tuberculosis problem, needs, and resources, so that local X-ray surveys may have efficient use and maximum effect.

6. Adequate safeguards should be utilized to protect all persons from unnecessary radiation.

Personnel Time in Nursing Homes of Washington State

ELIZABETH LAMBERTY TUCKER, R.N., M.N., and MILDRED A. SNYDER, M.P.H.

THE PLIGHT of many older citizens has created a phenomenal interest in the role of the nursing home in the care of the sick and the aged. This interest has been fanned by the rising cost of long-term hospitalization, advances in medical care and rehabilitation, and changing cultural patterns and age distribution of the population. Official health and welfare agencies are devoting more time and attention to nursing homes. The embarrassing lack of information about present practices in these homes, however, has been a severe handicap in planning construction and licensing programs.

A national inventory in 1954 reported that Washington had 3.6 beds per 1,000 population in nursing homes providing skilled nursing care, or nearly 40 beds per 1,000 population over 65 years of age (1). These rates are higher than the rates for any other State. Washington was the only State in 1954 having more nursing home beds (8,964) than general hospital beds (8,423).

In 1951 a nursing home licensing law was enacted by the State legislature, and in that same year rules, regulations, and standards were adopted by the Washington State Board of

Health (2). A nursing home is defined in the law as "any home, place or institution which operates or maintains facilities providing convalescent or chronic care, or both, for a period in excess of 24 consecutive hours for three or more patients not related by blood or marriage to the operator, who by reason of illness or infirmity are unable properly to care for themselves."

The nursing home licensing law is administered jointly by the State department of health and 17 of the 37 local health departments. Public health nurses and sanitarians, under the direction of the local health officer, visit homes to assist and consult with the operator and to enforce the law and the rules and regulations. Where the local health department staff is small, personnel from the State department of health work directly with the nursing homes. In other localities, a State team consisting of a nurse and a sanitarian works with local health department staffs and arranges for additional consultant services in architecture, nutrition, or management, as needed. During 1955 there was an average of 4 public health nursing visits and 5 sanitarian visits to each home by State or local personnel.

The present study of personnel in nursing homes in Washington, undertaken in 1956, had three objectives:

1. To collect and analyze data on the number and kinds of personnel employed in the various types of nursing homes.

2. To develop from the analysis staffing guides and other related material for the various sizes and types of homes. Such guides can be used by public health nurses and nursing

Mrs. Tucker is nursing consultant in the hospital and nursing home section of the Washington State Department of Health, Seattle. Miss Snyder during the study was hospital and medical program representative, Division of Hospital and Medical Facilities, Public Health Service, in Region 9, San Francisco. She is now associate research technician with the California State Department of Social Welfare, Berkeley.

NOTE: RN=registered nurse; LPN=licensed practical nurse.

home operators in interpreting the following section of the Laws, Rules, Regulations, and Standards, which applies to all nursing homes: "The nursing service in the home shall be the responsibility of a person employed full time as a registered nurse or a licensed practical nurse, and who has had at least 2 years' experience. Additional personnel shall be employed when the size of the service requires it, in order to give adequate care to patients."

3. To provide data that can be used to compare nursing home practice in the State of Washington with that in other States.

Collection of Data

Every year, as part of the application for renewal of license, due July 1, each nursing home must complete a weekly employee work schedule. Reported on this form are identifying data on the home, names of all employees and of the operator, hours and time of work, and type of position held by each employee, together with the license number of each registered nurse and licensed practical nurse. Included on the application for renewal are data on bed capacity, number of patients, type of home, and average daily census. From forms submitted in 1956, covering a 1-week period in May of that year, data were obtained for the study. With the assistance of the public health statistics section of the State department of health, the information was coded, punched on tabulating cards, and summarized.

Since the data were required for renewal of the nursing home license, information was obtained on all nursing homes. Similar reports

have been required for the past 6 years, and frequently the data have been verified during regular public health nursing visits to the homes. For this reason, the data collected appeared to be more complete and accurate than would be expected from a questionnaire. The reporting of licensed nursing personnel is believed to be reliable because the license number for each nurse had to be included and could be verified. However, the work classification for other types of personnel, particularly in small homes, was difficult to do and probably not too accurate.

In May 1956 there were 9,680 nursing home beds in the State. The 558 beds located in nursing home units in general hospitals were excluded from the study. Information was collected from 300 licensed nursing homes and homes for the aged, which provided 9,122 beds for patient care.

Types of Homes and Patients

The Washington State Department of Public Assistance has established four groups of nursing homes as a basis of payment for nursing home care of welfare patients. A home is classified as I, II, III, or IV according to the qualifications and number of skilled nursing personnel employed in the home. The requirements for skilled nursing personnel and the rate of payment for patient care for each type of home are shown in table 1.

Medical examiners, employed by the department of public assistance, examine welfare patients, classify them into four groups, and recommend the type of nursing home care

needed. Arrangements are then made for the care of patients in homes that have the appropriate skills available. In general, patients in the four types of homes meet the following criteria:

The group I patient is usually confined to bed unless lifted out, must be fed, or helped in feeding, and cannot assist in bedmaking, bathing, or caring for himself. He may be incontinent, in need of special diet, or in need of skilled nursing service such as intravenous and oxygen therapy or special dressings.

The group II patient is usually confined to bed unless lifted out, can assist with bedmaking by rolling from side to side, and may be capable

of feeding himself. He may, however, be incontinent and require parenteral medication or a special diet.

The group III patient may be on bed rest but have bathroom privileges, feed himself, and have a minor modification of a regular diet, or he may be ambulatory and require only semi-professional nursing service.

The group IV patient is usually ambulatory, sitting up frequently, and may require simple nursing services such as oral medication and routine observation. He may present a mild mental confusion.

Pertinent to analysis of the data on personnel in Washington's nursing homes are background

Table 2. General characteristics of nursing homes in Washington, May 1956

¹ Includes 58 operators who are registered nurses and 91 operators who are licensed practical nurses. Some homes reported more than 1 operator.

data relating to size of the homes and other general characteristics. Such data for the 288 homes classified into one of the four groups are shown in table 2. Group I and Group III homes far outnumbered the other two types. Homes in group I tended to be larger than those in any other group, and they had more patients than even the more numerous but generally smaller homes in group III. All groups had almost a full complement of patients, the average occupancy ranging from 85.3 percent for group IV homes to 95.6 percent for group I homes.

Most of the patients in the nursing homes were welfare patients: The proportion in group I was about three-fourths and in each of the other three groups about four-fifths. The majority of the welfare patients in each type of home met the criteria for that type. For example, nearly two-thirds of the welfare patients in group I homes had a group I classification, while the other third were classified group II, group III, or group IV.

Twelve of the homes, providing 219 beds, were not classified by the department of public assistance. Although the number of personnel in these homes is reported, data on personnel time are not presented.

Types of Personnel

In May 1956, 4,074 persons were employed full time or part time in the 300 nursing homes in this study (table 3). Nurse aides and orderlies were the largest group, about 40 percent. Dietary personnel (cooks, kitchen helpers, dishwashers, and pantry girls) were the second largest group. There were 508 registered nurses and 462 licensed practical nurses employed during the study week. Two-thirds of these skilled

nursing personnel were employed in group I and group II homes, where the patients generally require 24-hour skilled nursing care and supervision. There were 307 persons reported as operators of nursing homes, of whom 58 were registered nurses and 91 were licensed practical nurses. The average number of hours worked during the study week for all employees, including both part-time and full-time personnel, was 37.7 hours.

The percentage of employees who were registered nurses varied from 17.5 in group I homes to 5.0 in group III homes (table 4). In group I and in group II homes, about one-fourth of the employees were skilled nursing personnel; in group III and in group IV homes, nearly one-fifth were in this category. Approximately two-fifths of the employees are classified as nurse aides and orderlies in all types of homes, except group IV, where only 16.7 percent are so classed. More than 60 percent of the employees in group IV homes were classified as "all other."

Personnel Time Per Home

The data reported on the number of hours of employee time were analyzed separately for each group of homes and are presented in that fashion in this section. Although comparisons can be drawn among the groups, each type is considered here as a distinct entity.

Group I

The average number of hours of employee time per home per week varied from 394 for homes with 12-20 beds to 1,393 for homes with 61-129 beds (table 5). Total employee time increased as the size of the home increased. However, registered nurse time did not increase

in this manner. The number of registered nurse hours per home per week in the 3 size groups with 40 beds or fewer averaged essentially the same as the requirement of 112 hours (day and evening shifts 7 days a week). Homes in the 2 size groups with 41 beds or more exceeded this requirement. In all sizes of homes, the requirement of 56 hours of licensed practical nurse time (night shift 7 days a week) was exceeded.

In group I homes, the duties of the registered nurse are largely those of supervision and teaching of the other nursing staff and, in some homes, include managerial or administrative tasks. Direct service to patients generally consists of administering medications, performing highly technical nursing procedures, and observing the patients. Since the pattern of registered nurse staffing appeared to be related to the requirement rather than to the size of the home or the functions of the nurses, further analysis of registered nurse hours was made (table 6).

Fifteen of the group I homes did not meet the minimum of 112 hours of registered nurse time; four of these homes had 41 beds or more. Nineteen group I homes, 16 of which were larger than 40 beds, reported more than 155 hours of registered nurse time per week. While the

registered nurse hours per home ranged from 50 to more than 215, 42 homes reported between 110 and 124 hours, approximately the required amount. From the work schedules, it was noted that a number of homes employed 2 full-time registered nurses and 1 or 2 part-time registered nurses for relief on the day and evening shifts. The specific requirement appears to have a great

influence on the employment of registered nurses in homes with 40 beds or fewer, but larger homes tend to employ more registered nurses than the minimum.

To remove the effect of the size of the home in analyzing registered nurse time, the hours reported for each home were divided by the number of beds. The average number of hours of registered nurse time per bed per 7-day week is shown in the tabulation below. The range was rather wide, but nearly two-thirds of the homes reported between 2.0 and 3.9 hours of registered nurse time per bed.

Total-----	97

NOTE: Includes registered nurse operators. No deductions were made for managerial duties.

Group II

The average number of hours of employee time per home per week was 574. Of this amount, 74 hours was registered nurse time and 83 hours was licensed practical nurse time (table 5). The public assistance requirement is 56 hours of registered nurse time and 112 hours of licensed practical nurse time per week. Thus the study data indicate that registered nurses were being employed rather than licensed practical nurses in some homes.

Most group II homes aspire to a group I classification, but because of physical arrangements within the home and staffing requirements, a group I classification is not always feasible or desirable.

Group III

The public assistance requirement for group III homes allows either a licensed practical nurse or a registered nurse to be in charge of nursing service. Forty-eight of these homes reported registered nurses and 103 reported licensed practical nurses in this position. In 41 of the homes the operator was either a registered nurse or a licensed practical nurse

and supplied the only skilled nursing time reported.

The homes in group III reported an average of 346 hours of employee time per home per week, 70 hours of which was skilled nursing time (table 5). The number of hours ranged from 64 for homes with 4-20 beds to 174 for homes larger than 60 beds. In all size groups the requirement for skilled nursing time was exceeded. As in group I homes, the amount of skilled nursing time did not increase as the size of the home increased for homes with 40 beds or less. However, homes with more than 40 beds did have additional skilled nursing staff.

Group IV

The 12 homes in group IV averaged 223 hours of employee time per home per week, much less than the average for any other of the 3 groups (table 5). There was an average of 49 hours of skilled nursing time and 37 hours of nurse aide and orderly time per home per week.

Some of the group IV homes were formerly boarding homes for the well aged. When some of the residents in such a home became ill, nursing staff was added and the home applied for and received a nursing home license.

Skilled Nursing Hours per Shift

In group I homes a registered nurse is required to be on duty at all times during the day and evening shifts. Nearly three-fourths of the hours reported for registered nurses in these homes were on these shifts (table 7). The distribution of registered nurse hours is similar for group II homes, although the proportion was slightly higher for the day shift. Approximately two-fifths of the licensed practical nurse time was for the night shift in both group I and group II homes.

In group III homes, either a registered or a licensed practical nurse is required to be on duty at all times during the day shift. However, 17 percent of the skilled nursing time was reported on the evening and night shifts. All of the skilled nursing time in group IV homes was reported for the day shift.

Nursing Time per Patient

To compare further the four groups of homes, the average number of hours of nursing

time available per patient per 7-day week was computed for each home. Nursing time includes the hours reported for registered nurses, licensed practical nurses, nurse aides, and orderlies. Group I homes averaged slightly more than 13 hours of nursing time per patient per week, with a range of from 2 hours to more than 26 hours (table 8). More than one-third of the group I homes reported 12.0 to 13.9 hours. In group II homes, the average num-

ber of hours per patient per week was nearly 12, and the range was 6.0 to 23.9 hours. In group III homes, the average was slightly more than 9 hours per patient, with a range of from less than 2 hours to more than 26 hours. More than two-fifths of the group III homes reported 8.0 to 9.9 hours. The average for group IV homes was about 6, with a maximum of 9.9.

¹ Includes the time of registered nurse staff and operators, licensed practical nurse staff and operators, and aides and orderlies; no deductions were made for managerial duties.

Some group III homes provided more nursing time per patient per week than some group I homes (fig. 1). The variation among homes in all groups was extensive. These findings may indicate, for example, that some group III patients have the same nursing needs as group I patients. Or they may indicate that group III nursing staff may not work as efficiently as the staff in group I homes where care is directed by skilled nursing personnel and which are generally larger and perhaps better designed for nursing care. Further interpretation, however, must await additional information on patients and their need for nursing care.

Two recent publications report data on hours of nursing time per patient in nursing homes or other institutions for the chronically ill or disabled. Although these cannot be compared directly with the data for the Washington nursing homes because of differences in study methods, in types of institutions included, and in definitions of terms, it is of interest to review them here. One of the reports, from a

Figure 1. Average nursing hours per patient per week, group I and group III nursing homes, Washington, May 1956.

study of Florida nursing homes in 1955, gives 16.1 as the average number of hours of nursing service per patient per week. In this study the actual time spent by employees giving nursing service to patients was counted (3). In the other publication, a book by Edna Nicholson (4), this information appears: “. . . the average amounts of bedside service time required to maintain minimum adequate personal attention and nursing care for the residents varied from approximately 1.25 hours per patient per day in the nursing department of an institution where all the patients were ambulant and comparatively self-sufficient to more than 5 hours per patient per day in two institutions filled with seriously disabled people.” Nicholson also states that an average of 22.89 hours of nursing staff time per patient per week was required for minimum adequate institutional care for chronically ill and disabled patients.

In order to evaluate adequately the relationship between skilled nursing time and other nursing time in the four groups of homes, hours reported for the three types of nursing personnel have been changed into minutes per patient per day (table 9). Group I homes provided an average of 44 minutes of skilled nursing time per patient per day, of which 28 minutes was registered nurse time; group II homes provided approximately the same amount of skilled nursing time, 43 minutes, but had less registered nurse time, 20 minutes. Group III

and group IV homes provided considerably less skilled nursing time than the other two groups. Group III homes provided an average of 27 minutes, while group IV homes provided 24 minutes of skilled nursing time per patient per day.

Since group I and group II homes provided an almost equal amount of skilled nursing time per patient per day, and since group III homes provided approximately the same amount of time as group IV homes, it would appear that there are two types of nursing homes in Washington, one type, made up of the group I and group II homes, providing skilled nursing care on a 24-hour basis, and the other type, made up of the group III and group IV homes, providing limited skilled nursing services and supervision. The data also suggest that the group I patient is similar to the group II patient and has almost the same nursing needs, and that the group III patient is similar to the group IV patient.

Staffing Guides

From the data reported in this study, it has been possible to develop staffing guides for “intensive care” homes (groups I and II) and for “limited care” homes (groups III and IV). For example, the study indicated that in group I homes with 31–40 beds there was an average of 115 hours of registered nurse time per week, 86 hours of licensed practical nurse time, 269 hours of nurse aide and orderly time, and 202 hours for other staff (table 5). To determine the number of full-time personnel on duty during a 7-day week, these data were

Table 9. Average number of minutes of nursing time per patient per day, according to type of nursing home, Washington, May 1956

Group III.....	79	27		52
Group IV.....	42	24		18

RN=registered nurse; LPN=licensed practical nurse.

Figure 2. Staffing guide for "intensive care" nursing homes.

divided by 40 (for a 40-hour work week). The results for this size group I homes indicated averages of 2.8 registered nurses, 2.1 licensed practical nurses, 6.7 nurse aides and orderlies, and 5 other employees. These averages were further analyzed in terms of the work shifts to be covered during the 7-day week and other factors. The numbers were then rounded to full-time equivalents to give the suggested number of employees in the staffing guides.

Guides were developed for a 35-bed and a 50-bed "intensive care" home (fig. 2) and for a 25-bed and a 45-bed "limited care" home (fig. 3). They provide for hours of time slightly above the averages reported in May 1956. This appears to be a realistic minimum since many homes already employ more staff than suggested. It should be recognized that the number and kind of staff needed in any particular home will vary in accordance with many factors. Some of the factors that need to be considered in evaluating the adequacy of

the staff are the type of patients and their need for skilled and other nursing care, the kind of facilities and equipment available, the abilities of each member of the staff, and the philosophy of the operator or management. Also to be considered are the type of medical and other rehabilitative services available, the social and recreational activities provided, and the number of volunteers used. The guides should be useful in working with new or potential nursing home operators, in evaluating staff in existing homes, and in working with other agencies.

For a 35-bed intensive care home the staffing guide provides for a registered nurse on the day and evening shifts and a licensed practical nurse on the night shift for each day of the week. It allows for 2 aides on the day shift, 1 aide on the evening shift, and 1 aide on the night shift. It also recommends an additional aide to cover the time when the workload is greatest. For homes smaller than 35 beds, aide time would be less, with the skilled staff per-

Figure 3. Staffing guide for "limited care" nursing homes.

haps performing nurse aide functions. The amount of skilled nursing time recommended is considered minimum because of the type of patient in intensive care homes.

For a 50-bed intensive care home the guide suggests that a registered nurse be on duty at all times and that, in addition, a licensed practical nurse be employed for the day shift. There would be 4 aides on the day shift, 2 aides on the evening shift, and 1 aide on the night shift. For homes larger than 50 beds additional personnel of all types probably would have to be added, and the staff organized into two or more nursing units.

For a 25-bed limited care home there would be a registered nurse on the day shift 5 days a week and a licensed practical nurse on the day shift 2 days a week and on the afternoon shift 3 days a week. The guide also allows for an aide for each shift. In a 45-bed limited care home an additional licensed practical nurse is suggested to provide for licensed practical nurse supervision on the evening shift and for relief of the registered nurse. There would be 3 aides

on the day shift, 2 aides on the afternoon shift, and 1 aide at night.

Summary and Conclusions

In the State of Washington, nursing homes have been classified into four groups, the classification depending upon the qualifications and number of nursing personnel. In a study in 1956, personnel time was analyzed as to type of service and number of hours and then related to size of the homes and number of patients.

The amount of nursing time available to patients in group I homes averaged about 13 hours but varied from 2 to more than 26 hours per patient per week (7 days). One-third of these homes provided 12.0-13.9 hours of nursing time per patient per week. Nursing time per patient per day in group I homes averaged 113 minutes, 44 minutes of which was skilled nursing time.

Group II homes averaged 12 hours of nursing time per patient per week, with a range of from 6.0 to 23.9 hours. There was an average of 102

minutes of nursing time per patient per day, 43 minutes of which was skilled nursing time.

More than two-fifths of the group III homes reported 8.0 to 9.9 hours per patient per week, with an average of slightly more than 9 hours. The average number of minutes of nursing time per patient per day was 79, 27 minutes of which was skilled nursing time. Group IV homes had a maximum of 9.9 hours per patient per week and an average of 42 minutes per patient per day. Skilled nursing time in these homes averaged 24 minutes per patient per day.

Thus, group I and group II homes are quite similar in total nursing time and in skilled nursing time. There is considerable difference, however, between these two groups and groups III and IV. These two facts suggest the recommendation that there be only two types of nursing homes: intensive care homes, which provide skilled nursing care 24 hours a day, and limited care homes, in which a registered nurse or a licensed practical nurse is in charge of nursing service but not necessarily on duty at all times.

This study has demonstrated that specific requirements for skilled nursing staff influence the staffing patterns, particularly in small homes. In spite of the shortage of nurses, 24-hour skilled nursing supervision in "intensive care" homes has been required in Washington since the licensing program began in 1951. In "limited care" homes, one full-time skilled nurse in charge of the nursing service has been required. Almost all homes meet these standards, and many large ones exceed them. It is recognized, of course, that an official standard or requirement alone does not bring nurses into employment. Pleasant working conditions, intelligent personnel policies, adequate salaries,

and convenient location and hours have all contributed. The present standards for skilled nursing staff appear to be realistic, and it would seem that they could be increased if indicated. Staffing guides based on data presented in the study have been developed for the recommended types of nursing homes.

The data obtained in this study raise a number of questions that will require collection of additional information. Before requirements for skilled nursing staff are changed, it is essential to learn more about the needs of patients cared for in nursing homes. Such data should be related to the information reported here and also to the specific functions of various personnel, the design of the home, and the equipment available.

This study points up one of the values of good working relationships among local health departments, welfare departments, State and local nursing home associations and nursing home operators. A cooperative effort is necessary to obtain data that can be used in planning and operating programs to improve patient care in nursing homes.

Life Without Dobbin

A group of farmers in Voinjama, northwest Liberia, live without any domestic animals except chickens. Trypanosomiasis, or sleeping sickness, has ravaged the region for centuries, leaving only chickens and a few goats as survivors. There are no jungle ungulates; in fact, it is said that in all of Liberia there are only two horses. Although the people have adjusted, the human economy is chronically handicapped by the lack of domestic animals.

—EUGENE P. CAMPBELL, M.D., *chief, Public Health Division, International Cooperation Administration.*

Doctor's Holiday

On a busman's holiday, Dr. Arno E. Town culminated his visit to Ganta, Liberia, by treating Liberian patients. Despite advance notice of his visit, a frantic chase at the last minute was necessary to collect 10 patients for him to examine. Most were beyond help but he operated on one patient for cataract. Among the local tribes many more people were treated and given instruction. The noted Philadelphia ophthalmologist was in Liberia as a guest speaker of the Northern Liberia Medical Association.

—JOHN S. MOOREHEAD, M.D., *formerly chief public health officer. U. S. Operations Mission, Liberia.*

A Well for Ricaurte

When the rural environmental sanitation program was extended to Ricaurte, Ecuador, 15,000 people attended five health film showings and villagers donated their labor to excavate a well. Interested citizens formed a large subcommittee on health. The zone health department cooperated by supplying the

services of a medical officer, sanitary inspector, and microscopist.

Ricaurte is the site of the first activities of the sanitation program in Azuay-Canar, a village near Cuenca. Health and education servicios are carrying out a community-school improvement program in the village.

Malariologist's Reward

Children in the malaria-ridden villages near Chiangmai, Thailand, were so used to having malaria all the time they didn't even know they were ill, *but their blood was pale and their spirits depressed.* I watched school children suffering from enlarged spleens and high temperatures trying to study and play.

In the same area 3 years after the malaria control program began, smiling children, literally blooming with health and energy, lined up for examination. As they marched toward us, my colleagues and I cheered spontaneously, anticipating triumphant findings.

Our cheering was justified! Not one of the children was infected although they lived in the heart of a previously malarious district.

—MELVIN E. GRIFFITH, M.D., *chief malariologist, U. S. Operations Mission, Thailand.*

"Kan Ho Won" Replaces "Kan Ho Bu"

"Kan ho won" will replace "Kan ho bu" if Korean nurses have their way. The term correctly used for "nurse" is "kan ho won" which means "a person who has been trained to give care and protection." At their annual meeting in Seoul the Korean Nurses Association drafted a letter requesting government authorities to use "kan ho won" rather than the old Japanese-imposed term, "kan ho bu," a woman who gives care and protection.

A "kan ho won" for 37 years, Mrs. Hyo Chung Lee, chief nurse at the Masan Tuberculosis Sanitarium, was the first Korean to receive the Florence Nightingale Medal.

—ALBERT P. KNIGHT, M.D., *chief, Health Division, U. S. Operations Mission, Korea.*

Continuity of Patient Care

CONFERENCE REPORT

MORE effective means of transmitting information between hospitals and public health nursing services in order to provide continuous care for patients was the subject of a conference held in Chicago on May 11 and 12, 1956, under the sponsorship of the departments of hospital nursing and public health nursing of the National League for Nursing.

The main aim of the conference was to encourage planned nursing services in hospitals and in agencies providing home care, although community planning was also emphasized.

Basic to all other considerations is the mechanism by which information relating to the patient's physical, psychical, and social circumstances may be transmitted as the patient moves between hospital, clinic, and home. The conferees agreed that one person, acting as coordinator and administrator, in each institution must be responsible for the effective administration of the program. All reports concerning the patient should be written, with "feedbacks," or written responses to reports, a necessary part of a fluid communication system. Conferences were recommended for the workers when the patient is admitted and discharged.

The chief concern of community planning would be to promote understanding by means of conferences, articles, and cooperation among various groups sharing the same interests. With an efficient planning committee, community needs could be ascertained in terms of the extent of service to be provided for the patient. The committee could also determine, if necessary, priority cases. In addition, the commit-

tee should establish a standard referral form, acceptable to all participants, for transmitting information.

Backgrounds for discussion were supplied by Dr. George A. Silver, chief of the division of social medicine, Montefiore Hospital, New York City; Doris Schwartz, instructor in outpatient nursing, Cornell University-New York Hospital School of Nursing; and Dr. Bess Sondel, professorial lecturer in communication, University of Chicago.

Silver, believing that "good patient care calls for attention to physical, emotional, and social factors, for consideration of what will happen after the patient leaves the hospital, for example, and of what happens before the patient comes to the hospital," stressed the need for nurses to play more extensive roles in patient care. Before they can, however, two ideas must be generally accepted, Silver pointed out. First, the nurse "needs to be involved in planning, consulted on progress, and advised of developments." Second, "the nursing part needs to be admitted into rational organization of medical care."

Given a greater role to play, the public health nurse can provide information about the patient and his family which would be welcome to the hospital nurse, while the latter, with her special knowledge of the patient's attitude toward his illness, himself, and his family, could facilitate aftercare and rehabilitation by transmitting her information to the public health nurse.

The patients who Silver feels to be most in

need of continuous care are new mothers and infants, the tuberculous, cardiacs, hemiplegics, and diabetics, those subjected to radical or mutilating surgery, the aged, the mentally ill, and children suffering from long-term illnesses.

The nursing service, he asserted, "must now organize its services to the sick so as to include a continuity of concern in and out of the hospital." He emphasized the need for a discharge planning conference to establish a bridge between private and public nursing services. The discharge planning conference would enable the doctor, nurse, social worker, nutritionist, and physical and occupational therapist to describe the obstacles and adjuvants to continuing patient care in the home. Furthermore, information coming back, after a patient has been at home for a time, will provide additional educational material for all those participating in the conference. It is important to the field nurse's morale, Silver added, that her reports be read and answered.

Miss Schwartz gave a brief history of a referral system begun in 1939 between the Henry Street Visiting Nurse Service and the New York Hospital, and expanded through the years until, in 1946, the Greater New York Interagency Referral System was established.

The objective of a good referral system, Schwartz declared, is to provide continuous nursing care. Such a referral system implies well-established communication lines, planned conferences, visits to patients' homes before discharge, and the establishment of a close relationship among those professionally involved.

In order to make a referral system work, continuous nursing care must be seen as a legitimate nursing function, and as the kind of care that can be provided by good liaison between the hospital and the community nursing agencies. And it should be adopted as a goal that "no patient who would benefit by public health nurs-

ing referral, following a hospital or clinic experience, should go unnursed or poorly nursed through the failure of nurses to consider the appropriateness of such a referral."

If the patient's problems are kept central, Schwartz believes, any antagonisms which may arise among the groups can be overcome.

Samples of interagency referrals were provided. These referrals include reports by the physician, hospital nurse, physical and occupational therapists, dietitian, medical social worker, and public health nurse.

Sondel described the exercise of feedback as a means of improving communication. Unless a communicator is able to learn how her information is received and interpreted, she is unable to judge whether or not she is being understood, and whether her purpose in giving information is being carried out. Through feedbacks from those who have used the information, a nurse learns to see her work in relation to that of others, gains greater understanding of the importance of sharing information, and learns how to make her reports more helpful to others. It is important, therefore, that a means of reporting back on information received be provided.

Sondel discussed the effect of nonverbal communication, the flexibility needed to acquire deeper understanding of what is communicated to an observer, and the stability in discourse which is obtained from a critical examination of the patterns words make, with reliance upon one's own examined pattern.

A summary of the conference, including verbatim accounts of the addresses, is available to the public. Published as "Hospitals and Public Health Nursing Services Plan Better Care," it can be purchased for \$1.00 from the Department of Public Health Nursing, National League for Nursing, 2 Park Avenue, New York 16, N. Y.

Public Health Reports, published
1878 under authority of an act of
Congress of April 29 of that year, is
published monthly by the Public Health
Service pursuant to the following autho-
rity: United States Code, title 42,
sections 241, 245, 247; title 44, section 4
Use of funds for printing this publica-
tion approved by the Director of the
Bureau of the Budget, August 24, 1957.

U. S. DEPARTMENT OF HEALTH, EDUCATION, AND WELFARE

MARION B. FOLSOM, *Secretary*

PUBLIC HEALTH SERVICE

LEROY E. BURNEY, *Surgeon General*

ASIAN **VARIANT**

INFLUENZA **TYPE A**

In the fall of 1957 the United States experienced the most extensive influenza epidemic in 40 years. This, in itself, is a historical event of major medical and public health significance. Equally significant is the fact that for the first time in our history the Nation was making real preparations for an epidemic before it appeared.

Although morbidity and mortality rates, as was predicted, did not equal those of the 1918 pandemic, we shall never know, precisely, the total who were incapacitated or the real impact on the national economy. That it was substantial is indicated by the samplings taken by the U. S. National Health Survey, which showed that more than 80 million Americans suffered from illness of the upper respiratory tract between July 1 and December 1, 1957,

of such severity that they had to spend one or more days in bed. While all of these cases were obviously not Asian influenza, it is reasonable to assume that the illness accounted for the majority.

At the time at which this is written—in late December—it would appear that the epidemic has pretty well run its course in the United States. Opinion differs on the possibility that by the time this appears we may be experiencing a second wave; and a substantial amount of Asian influenza is anticipated during the midwinter months.

The fairly rapid decline in new cases during late November indicated that the first wave was over; and that the time was appropriate for a provisional summing up of our national experience with this epidemic.

Historical perspective will provide more definitive conclusions than are reached in the following pages. The story as it is here recorded, however, will be of interest to the public health profession and may well suggest guidelines for meeting similar health problems in the future.

To me, one of the most significant things about our national experience has been the demonstration of how quickly and effectively our national medical and health resources can mobilize to combat the threat of nationwide illness. The keynote of the whole program, in fact, has been the cooperation of the many toward a single goal. I do not know of another instance in our peacetime history in which so many of the elements of our society, in so short a time, have joined together to identify a health problem, determine the means for its solution, and to work toward resolving it.

These elements have included the agencies of the Federal, State, and local governments, notably, the Department of the Army, which first isolated and identified the Asian influenza virus, the medical and public health profession, professional societies, the voluntary health agencies, the pharmaceutical manufac-

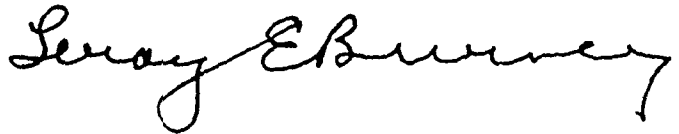

turers, advertising, and, in full measure, the press, television, and other media of professional and public information and education.

Throughout this report, the contributions of these groups and others are noted. It is not inappropriate to extend to all of them and to the hundreds of individuals who have worked on the problem, a word of appreciation on behalf of their fellow Americans.

I mentioned earlier the statistics of incidence. Certainly it was substantial. The rapid production and distribution of the vaccine during the fall months, however, unquestionably reduced the impact of the epidemic. Many millions of persons, we can be certain, did not contract Asian influenza because of the protection of the vaccine.

This issue of *Public Health Reports* includes a report on the Asian influenza epidemic and the steps taken to study and control it. The report suggests, among other things, that the profession and structure of public health are stronger as a result of our experience with the Asian influenza epidemic of 1957.

More important, it provides a document which, under study, may yield knowledge on how we can do a better future job for the people of the Nation in whose cause we serve.

Administrative History

of

THE ASIAN INFLUENZA PROGRAM

WILLIAM H. STEWART, M.D.

THE ASIAN INFLUENZA program of the Public Health Service, at this writing, would appear to fall, chronologically and functionally, into four phases. The first, a period when information was received and policy issues were broadly delineated, began in the spring of 1957 and ended with the first meeting of the Surgeon General's Advisory Committee on Influenza on June 10.

As the disease occurred sporadically in the United States during the summer, the Public Health Service deployed its resources to maintain surveillance, conferred with manufacturers on problems of vaccine production, determined the requirements of alternative courses of action, and secured the cooperation and financial support necessary to institute the program finally adopted. This developmental phase, as it may be characterized, came to an end late in August.

Dr. Stewart, Assistant to the Surgeon General, has served as liaison for the influenza activities of the Office of the Surgeon General, Public Health Service.

On August 27-28, 1957, the State and Territorial health officials met in Washington at the request of the Surgeon General. The virus was then widely seeded across the Nation, the licensed influenza vaccine manufacturers were in full-scale production, and the medical, hospital, and public health authorities of the Nation, through their professional organizations, had made plans to mobilize their resources in the event of a large-scale epidemic. After reviewing this progress, the health officers concurred in the decisions taken and called for further specific action by the States and the Public Health Service.

We are currently in the operating phase of the Asian influenza program, a phase perhaps drawing to a close. At some time in the spring of 1958, a year more or less after Asian influenza was first reported, the retrospective evaluations will begin. This fourth and final phase may well be lengthy, for the Asian influenza episode is unique in the history of public health and deserves the thoughtful consideration it is certain to receive from students of

medicine, epidemiology, virology, immunology, public health administration, and health education.

This chronicle records administrative aspects of the Asian influenza program of the Public Health Service, from the viewpoint of the Office of the Surgeon General. It will deal only with the first two periods categorized above, the administrative problems of the latter two phases being relatively commonplace. Administrative issues presented in the early months of the program, however, were unprecedented and therefore require elucidation.

Nation Alerted

As is well known, the initial laboratory work on the Asian influenza virus was performed, with exemplary initiative and speed, by the Army: the 406th Medical General Laboratory in Japan and the Walter Reed Army Institute of Research in Washington, D. C. The results of this work were communicated at once by the Army virologists to their counterparts in the Public Health Service, with whom they are in continuing close professional contact. The situation first came to the attention of the Office of the Surgeon General on May 20, 1957, when the director and an associate director of the National Institutes of Health reported orally to the Acting Surgeon General that epidemic influenza with unusually high attack rates was being reliably reported from Asia.

The Deputy Surgeon General, who was at this time acting head of the Public Health Service because the Surgeon General was in Geneva at a World Health Organization meeting, designated the associate director of the National Institutes of Health, a virologist, as technical point of contact for the Surgeon General with respect to the developing influenza situation. The Acting Surgeon General next informed the Assistant to the Surgeon General for Information and designated a medical officer to maintain special liaison with the Institutes.

On May 22, the National Office of Vital Statistics submitted a memorandum summarizing reports of the spread of the disease. During that first momentous week, the staff of the

Special Assistant for Health and Medical Affairs to the Secretary was being kept apprised of the situation. From the National Institutes of Health came a report of a "dry run" exercise in vaccine production conducted by the manufacturers with the "London" strain in 1951, as well as a memorandum from the director of the Division of Biologics Standards outlining the technical steps that must precede mass immunization with a new vaccine. More specific information with respect to potential vaccine production was requested from the National Institutes of Health.

When the bureau chiefs met for their regular staff meeting with the Office of the Surgeon General on May 28, the Army had supplied Asian strains of the influenza virus that were not compatible with previously known strains. The National Institutes of Health had made the new strains available to licensed vaccine manufacturers, in accordance with established procedure, so that they could prepare to incorporate them in the polyvalent influenza vaccine then being produced, if this were deemed desirable.

The Acting Surgeon General recalled that when the Armed Forces began routine annual influenza immunization in 1954, the Public Health Service did not recommend comparable immunization of the general public. This decision was rooted in the relatively short duration of demonstrated immunity and lack of assurance that strains in the polyvalent vaccine would be the ones responsible for future epidemics. However, the Acting Surgeon General now believed it necessary to reexamine, in the light of later developments, the bases of Public Health Service policy on immunization of civilians against influenza. The Bureau of State Services and the National Institutes of Health were therefore asked to confer and to forward an analysis and recommendations.

Formal Public Health Service participation in the national common effort began on May 28 at a conference called at the requests of the chiefs of preventive medicine of the three military services to consider the control of influenza caused by the new strain of virus which had been first reported from Hong Kong on April 17. The Public Health Service was rep-

Walter Reed Army Medical Center

resented by an associate director of the National Institutes of Health and the director of its Division of Biologics Standards.

The conference was informed that the disease was clinically mild with high attack rates on naval vessels and among civilians. Laboratory evidence indicated that the virus responsible was, for practical purposes, antigenically new; antibodies to it were absent in both animals and humans who had been highly immunized naturally or artificially against preceding strains of influenza virus. The virus had already reached the United States, in the opinion of the group, but the disease was not expected to reach major epidemic proportions until fall.

The conference recommended to the military Surgeons General that the Department of Defense procure about 3 million cubic centimeters of a monovalent vaccine containing the Hong Kong strain of the virus, the desired strength of this vaccine being tentatively set

at 500 CCA units. September 1 was the target date recommended for the start of the vaccination program for military personnel. The Commission on Influenza of the Armed Forces Epidemiological Board was requested to propose as quickly as possible the composition of a polyvalent influenza virus vaccine to be used later in the year.

On May 29, the associate director of the National Institute of Allergy and Infectious Diseases forwarded a memorandum describing the Influenza Study Program of the World Health Organization and mentioning the probable need for an increase in the number of collaborating laboratories in the United States and for providing them with diagnostic reagents for detection of the Asian influenza virus. The director of the National Institutes of Health also submitted a memorandum, after consultation with the chief of the Communicable Disease Center, recommending that the monovalent vaccine desired by the Defense Depart-

ment be licensed; that the Communicable Disease Center furnish typing antisera to State laboratories; that State epidemiologists be advised to watch for outbreaks of Asian influenza; that the Epidemic Intelligence Service of the Communicable Disease Center promptly investigate reported outbreaks; and that "the role of influenza vaccine as a public health measure be carefully studied"

The chief of the Division of Foreign Quarantine also forwarded a memorandum to the Office of the Surgeon General on May 29. It advised that quarantine officers at Honolulu, Seattle, San Francisco, and Los Angeles were inspecting inbound traffic for influenza signs and symptoms and notifying health officials of their occurrence. Passengers were being asked their itineraries for 2 weeks before and after quarantine inspection, with notification of local and State health departments following when indicated.

After reviewing these documents, the Acting Surgeon General met with the Assistant to the Surgeon General charged with special influenza responsibilities and the deputy chief of Information Services. It was decided to call the Bureau of State Services and the National Institutes of Health representatives together for more collaborative analyses and recommendations than had yet been presented. The information function was represented at this stage because of the public's obvious "need to know" about the nascent influenza policies.

Two days later, on May 31, the Acting Surgeon General wrote: "Nothing about influenza is more certain than that new strains appear, presumably by mutation, and epidemiologists have postulated that the 1918 pandemic was the result of such a mutation and that another pandemic may arise at any time from the same phenomenon. The question then is simply whether the current situation is sufficiently unusual to indicate the possibility that this has occurred. This decision requires careful consideration by the epidemiologists. If it [the current situation] is unusual or almost unique, the burden of proof would seem to be on those who oppose the recommendation to press for a mass immunization against the new strain with all possible vigor." The Acting Surgeon General then requested the principal staff officers to consider

whether "the investment of the few million dollars necessary to develop and disseminate vaccine as widely as possible would be a logical step to recommend . . . if the current influenza situation was indeed unusual . . . [with] even a possibility of a widespread epidemic next fall."

Broad Planning

On the afternoon of May 31, officials of each bureau met with an Assistant to the Surgeon General to plan Public Health Service action with respect to Asian influenza. The conferees discussed coordination of Public Health Service activities, improvement of arrangements for influenza reporting, and influenza vaccine as a public health measure. The problems of producing a monovalent vaccine were compared with those of producing a polyvalent vaccine containing the new strain. The lack of comprehensive data dealing with effectiveness of influenza vaccines among the civilian population was noted.

The Division of Foreign Quarantine was asked to work closely with the Epidemic Intelligence Service of the Communicable Disease Center and to report all relevant information promptly to the National Office of Vital Statistics. The Communicable Disease Center was asked to alert State health departments and laboratories, intensify its influenza surveillance, and report its findings to the National Office of Vital Statistics, from whence information would be disseminated biweekly to all concerned in the Service and elsewhere. Announcement of the steps that were being taken would be released to the press on June 3 and an article alerting physicians prepared at once for the *Journal of the American Medical Association*. Meanwhile, the National Institutes of Health would continue work on problems of vaccine production. It was agreed that more time was needed to observe the course of the epidemic and progress in producing vaccine before it would be possible to give a mature judgment on the question of influenza immunization for the general public.

On June 5 the Division of Foreign Quarantine reported influenza aboard a civilian ship bound for San Francisco from the Orient. The Office of the Surgeon General was also advised

that inquiries had already been received from other Federal agencies and transportation lines concerning Service policy on use of the polyvalent influenza vaccine then available in small quantities through commercial channels.

Questions of this nature were discussed that day at a meeting called by the Assistant to the Surgeon General designated to deal with Asian influenza. Representatives of all bureaus were present. The associate director of the Institutes stated that the odds favored a mild epidemic in the fall or winter, but that there was some possibility of an epidemic on the order of the 1918 experience. The technical problem of vaccine production had been solved, he reported; a monovalent vaccine could be expected in September and a polyvalent vaccine incorporating an Asian strain a month later. Monovalent vaccine production had been started with purchases by the Department of Defense.

He suggested that certain groups, such as transportation, communications and utility workers, hospital personnel, and some Federal employees, receive the monovalent vaccine as soon as the Armed Forces. (A list of proposed civilian occupational priorities for vaccination against influenza had been prepared as part of the 1951 exercise.) These actions would not require additional funds. The deputy chief of the Bureau of State Services proposed that the Surgeon General seek the counsel of an advisory group representative of public health officials, practicing physicians, and the vaccine manufacturers. He foresaw advocacy by the Public Health Service of large-scale immunization, under certain conditions, and this would require additional expenditures.

The members of this meeting thereupon recommended that the Surgeon General confer with a representative professional group to ascertain its reaction to proposed recommendations by the Service that influenza vaccine be used generally in the civilian population and that certain special groups receive the monovalent vaccine as soon as it became available. No additional funds were believed necessary for these influenza activities. The advisers were to be told, however, that if the virulence of the virus increased or if the influenza case fatality rate turned upward, the Service would attempt to accomplish vaccination of all civilians. Au-

thority to divert funds would be requested in this unlikely event, and supplemental funds would be requested to replace any so diverted.

There was, of course, considerable correspondence and informal liaison with congressional committee staffs and with offices of individual Senators and Representatives throughout the period described in this report. In reply to many inquiries, on June 7, after his return to the United States, the Surgeon General wrote to the chairmen of the committees and subcommittees of the House of Representatives and the Senate which are responsible for substantive and appropriations legislation for the Public Health Service. He advised them of the developing situation and furnished a summary of events and actions taken, including an announcement of a meeting on June 10 of a special advisory committee of physicians and health officers.

The Advisory Committee on Influenza, which first met on June 10, included the secretary of the Executive Committee and the chairman of the Civil Defense Committee of the Association of State and Territorial Health Officers; the president of the Academy of General Practice and a member of the board of trustees of the American Medical Association; representatives of the American Public Health Association and the American Academy of Pediatrics; the director of the Commission on Influenza, Armed Forces Epidemiological Board, and a spokesman for the Division of Preventive Medicine, Office of the Surgeon General of the Army; and the Special Assistant for Health and Medical Affairs, Office of the Secretary of Health, Education, and Welfare. Officials of the Service with influenza responsibilities also attended, as well as a representative of the Children's Bureau.

General findings of the meeting were:

1. No major outbreaks were expected to occur before fall, although sporadic occurrence could be expected throughout the summer.
2. Since limited information suggested that the existing polyvalent vaccine was not effective against the new influenza virus strain, an effective monovalent vaccine should be produced as soon as possible.
3. Every effort should be made to test vaccines and to collect, study, and disseminate

information on the epidemiology of Asian influenza. Consideration should be given, but based on later and more complete information, to the use of a vaccine by the civilian population.

4. No change should be recommended in private physicians' practice in utilizing the existing polyvalent vaccine. Physicians should immediately report suspicious cases to their health departments so that any occurrence of suspected influenza could be investigated quickly.

5. The situation did not yet appear to justify establishment of priorities for civilian use of the vaccine or consideration of government subsidy in its production.

The gist of these findings was telephoned on June 10 to the regional medical directors, who were directed to telephone the same information to the chief State health officials in their region. The Surgeon General had directed that the States be kept fully informed with all possible speed. To this end, among other measures, the chief of the Bureau of State Services frequently telegraphed State health officials during the summer to alert them to influenza information in the *Morbidity and Mortality Weekly Report* and to report other developments.

After the meeting of the Advisory Committee on Influenza, the Surgeon General held a general press conference. (He and other members of his staff were accessible to individual reporters throughout the period described.) Interest of the press and public in influenza rose sharply as a result. The voluntary health organizations were immediately alert to the various eventualities inherent in the situation. On June 11, the managing director of the National Tuberculosis Association, for example, generously offered the cooperation of the association and its affiliates for the health education of the public, if this should become necessary. Similar messages were received from other large voluntary health and welfare associations and professional societies.

Tempo Intensified

The June 10 meeting, as has been noted, marked the end of the first phase of the Asian influenza activities of the Public Health Serv-

ice. After that meeting, the tempo of those activities increased markedly, as outbreaks of the disease increased across the Nation and as the time approached for decision on the major policy issues. As recognized on June 10, these were:

1. Whether to recommend vaccination and of what segments of the population.

2. Whether to rely on a monovalent or polyvalent vaccine, a complex question related to factors of effectiveness and supply.

3. The extent of further Public Health Service participation in influenza programs.

The second or developmental phase of Public Health Service Asian influenza activities opened with a meeting on June 12 of technical representatives of the vaccine manufacturers with the National Institutes of Health. The latest epidemiological information was presented to the manufacturers, with data on the influenza virus strains encountered and their growth characteristics. Each firm summarized its experience with the growth of the various strains used in the production of influenza vaccine.

The proposed strain constitution of vaccines for military and civilian use was then discussed. The proposed formulas for military monovalent and polyvalent vaccine caused no comment, but some discussion concerned the proposed polyvalent vaccine for civilian use. The manufacturers expressed a preference for a monovalent vaccine containing the Asian strain. There was general agreement that the low antigen yield of the Asian strain as measured in CCA units made it difficult to obtain material of sufficient concentration for inclusion in the proposed polyvalent vaccine. It was pointed out that much of the vaccine prepared for the coming influenza season had already been pooled, and the Asian strain could not be added because it could not be produced in high concentration. In view of this difficulty, each manufacturer agreed to review its inventory and submit as quickly as possible an evaluation of the formula that would make best use of the material at hand.

By June 17 the special weekly influenza report to the Surgeon General brought word of potency studies of monovalent vaccines conducted by the Virus and Rickettsia Section,

Walter Reed Army Medical Center

Electron microscope photograph of Asian influenza virus.

Communicable Disease Center, Montgomery, Ala. Such studies are essential for standardization of vaccines. The reactivation of the Inter-Service Influenza Advisory Committee, which had been recommended at the June 10 meeting, was also reported. The Armed Forces Epidemiological Board, the National Institutes of Health, and the Communicable Disease Center each planned to have an epidemic intelligence team ready on short notice to investigate influenza outbreaks anywhere in the world. The Division of International Health of the Public Health Service and the Regional Office of the World Health Organization made arrangements to facilitate the rapid departure of these standby teams. It will be recalled that at that time no isolation of the Asian strain

had yet been made in the United States. It was therefore important to learn as much as possible from epidemics abroad, looking especially for evidence of increased virulence.

The first report of Asian influenza in the United States came from the Navy by telephone on June 18. Aboard ships at the Naval Station at Newport, R. I., none of which had been in Far Eastern waters, the disease was running a course similar to that reported from the Orient and elsewhere.

Countering All Eventualities

On June 20 an Associate Director of the National Institutes of Health set down the following alternatives for the course of the disease and corresponding action to counter each:

1. *An explosive epidemic before September 1, 1957, with either (a) continued low mortality, or (b) increased virulence.*

Vaccination could not be considered, except for limited supplies of polyvalent vaccine and possible production for use in 1958.

A professional and public information program and mobilization of medical resources, both in cooperation with the American Medical Association, would be imperative.

Expansion of epidemic intelligence and diagnostic laboratory networks would be essential.

2. *Sporadic local occurrence during the summer with an explosive epidemic during the winter, again with*

(a) *continued low mortality.*

Vaccination of priority groups, as many as 6 million people, would be indicated.

A professional and public information program and mobilization of medical resources, both in cooperation with the AMA, would be imperative.

Expansion of epidemic intelligence and diagnostic laboratory networks would be essential.

(b) *increased virulence.*

Maximum vaccine production and immunization would be required, with priority groups vaccinated first.

A professional and public information program and mobilization of medical resources, both in cooperation with the AMA, would be imperative.

Expansion of epidemic intelligence and diagnostic laboratory networks would be essential.

3. *Sporadic local occurrence during the summer with a winter of normal influenza incidence.*

No recommendation of influenza vaccination would be indicated.

Expansion of epidemic intelligence and diagnostic laboratory networks would still be essential.

The appropriate staff members were directed to develop the personnel, financial, and legislative requirements of these alternatives.

The logical possibilities set down in this form represent the alternatives then facing the decision-makers in the Public Health Service and elsewhere. The consensus in the Public Health Service during the middle of June was that the most probable outcome would be sporadic local occurrence during the summer with an epidemic during the fall or winter that would result in a relatively small increase in mortality. A widespread epidemic before Labor Day with low mortality was considered a reasonable possibility, but the odds against this event were believed to be greater than those favoring a benign epidemic later.

The hypothesis that the Nation would experience a winter of normal influenza incidence

was considered wishful thinking. On the other hand, a repetition of the notorious pandemic of 1918 was also considered most unlikely, with probabilities of 1 in 20 to 1 in 40 against such an event. It could not be overlooked, however, that, historically, pandemic influenza of high mortality has recurred at intervals of about 20 years, and there had been no such experience for 39 years.

It was clear at this time that quantities of potent vaccine sufficient for large-scale immunization could not be anticipated until after the middle of August. If an epidemic occurred before Labor Day, with either mild or extreme mortality, there would be virtually no vaccine available. If the epidemic developed during the fall and winter, as seemed most probable, it would be possible to immunize a substantial segment of the population, provided that vaccine production was at a high level during the summer and fall. This would assure continuity of essential civilian services and protect those vaccinated against the discomfort and danger (relatively high for aged persons and those with a history of chronic respiratory or cardiac disease) of an attack of influenza. Production of large quantities of vaccine was also indicated to protect against the possibility of increased virulence of the Asian strain.

The framework of alternatives and the reasoning described above was presented to the Secretary of Health, Education, and Welfare on June 24, with preliminary estimates of probable cost of each possibility and new legislative authority that might be needed. On June 26 the Surgeon General met with representatives of the American Medical Association to describe the progress of the disease toward this country and discuss the question of medical manpower in the event of a serious epidemic. The outlook for immunization against influenza was also discussed, and the alternative types of Federal action envisaged by the Service were described. It was made clear that the situation did not appear to warrant large-scale vaccine purchases or subsidization of production by the Government. Agreement was then reached on the conduct of a joint Public Health Service-American Medical Association cam-

paign of public information and health education. News of Asian influenza was on the front pages and television screens, but the public had not learned what it could do to protect itself. The association was represented at this meeting by two trustees, the chairman of the Committee on Civil Defense and the assistant secretary-general manager.

On the next day the National Institutes of Health reported plans for research on influenza that would take advantage of the unique opportunities expected during the 1957-58 season. These plans included clinical studies of patients experiencing epidemic influenza, with particular emphasis on cardiovascular and systemic manifestations; studies of the factors contributing to elevated influenza mortality among aged or debilitated patients; and studies of the disease among vaccinated civilian communities. Not only was it possible to support these research projects with funds previously made available, but no additional funds were requested by the National Institutes of Health for its influenza vaccine studies, microbiological studies of patients with influenza, or laboratory studies and normal statutory control of vaccine production.

On July 1 the Surgeon General's weekly memorandum to the Secretary's Special Assistant for Health and Medical Affairs reported a number of civilian cases in the United States that were believed to be Asian influenza, although it had not been possible to obtain laboratory confirmation of the tentative diagnoses. Influenza diagnostic reagents had been shipped to all domestic laboratories in the WHO Influenza Program, however, and improvement in the reporting of confirmed cases was expected. Advices from abroad indicated that morbidity and mortality rates were unchanged.

On July 2 officials of the Bureau of State Services and the Bureau of Medical Services discussed the possibility of an influenza outbreak at the International Boy Scout Jamboree to take place at Valley Forge, Pa., July 12-18. More than 50,000 Scouts were expected from all parts of the Nation and abroad. Physical examinations were to be made on arrival, a satisfactory physician-Scout ratio would exist, and as many as 25,000 hospital beds could be fur-

nished in the vicinity by military, private, and Federal Civil Defense Administration hospitals, if an epidemic should develop. In addition to the Public Health Service, military, Scouter, and local civilian physicians, representatives of the State health department, and CDC Epidemic Intelligence Service officers were to be on the scene. These precautions were considered sufficient. During the Jamboree a few hundred Scouts were hospitalized because of upper respiratory infections, but this was not much more than normal incidence, in the opinion of the chief medical officer for the encampment, a physician from the PHS Hospital, Stapleton, N. Y. Confirmed cases of Asian influenza were largely confined to Scouts from California and Louisiana.

On July 3 the director of the National Institute of Allergy and Infectious Diseases was designated the "focal point" at the National Institutes of Health for influenza matters. NIH influenza research and licensing responsibilities involved the National Institute of Allergy and Infectious Diseases, the National Heart Institute, the National Institute of Mental Health, the National Institute of Neurological Diseases and Blindness, the Division of Biologics Standards, the Division of Research Grants, and the Clinical Center.

Confirmed Civilian Cases

Word came from the California State health officer on July 9 that laboratory results indicated Asian influenza as the cause of an outbreak of acute respiratory illness that had affected 200 teen-agers meeting at Davis, Calif., late in June. These were the first confirmed civilian cases of Asian influenza in the United States. Another outbreak then under investigation involved young people from 43 States and 10 other countries who had gathered at Grinnell, Iowa. Asian influenza was later proved in the laboratory to be responsible for this outbreak also, and it was further established that one of the young people at the Davis meeting afterward attended the Grinnell gathering.

An assistant to the Surgeon General met with officials of the American Medical Association in Chicago on July 9 to discuss recommenda-

tions with respect to influenza that were then being drawn up for action by the trustees of the association. The activities discussed at this meeting and later authorized by the trustees included professional information and education through the AMA publications, preparation of public information materials (in cooperation with the Public Health Service) for use when necessary, and standby plans by State and county medical societies to deal with serious epidemics.

On July 9 the Communicable Disease Center issued the first of a series of weekly reports summarizing laboratory information and epidemiological data reported by State health departments, Epidemic Intelligence Service officers, collaborating influenza diagnostic laboratories, and other sources.

On July 10 the Service announced establishment of specifications for manufacture of vaccines containing the Asian strain. On the same day the Executive Committee of the Association of State and Territorial Health Officers met in Washington, D. C., with Service officials. Influenza was discussed at length, with the Service urging more complete reporting from local sources and full utilization of laboratories for definitive diagnosis of the disease. The health officers agreed that the Public Health Service and the American Medical Association should conduct a vigorous campaign of public information and health education urging immunization against influenza. In the past, influenza vaccines had been used, for the most part, by large firms for the protection of their employees. However, the potential dangers accompanying a large-scale epidemic, which now appeared highly probable, made it advisable to stimulate wider use of the only preventive available.

On July 11 the Public Health Service consolidated recommendations from its bureaus and meetings with outside groups and developed proposals for further action against Asian influenza. These were submitted to the Secretary of Health, Education, and Welfare on the following day.

In Geneva on July 11, during the Fourth International Poliomyelitis Congress, the chief of the Endemoepidemic Diseases Section of the World Health Organization called an informal

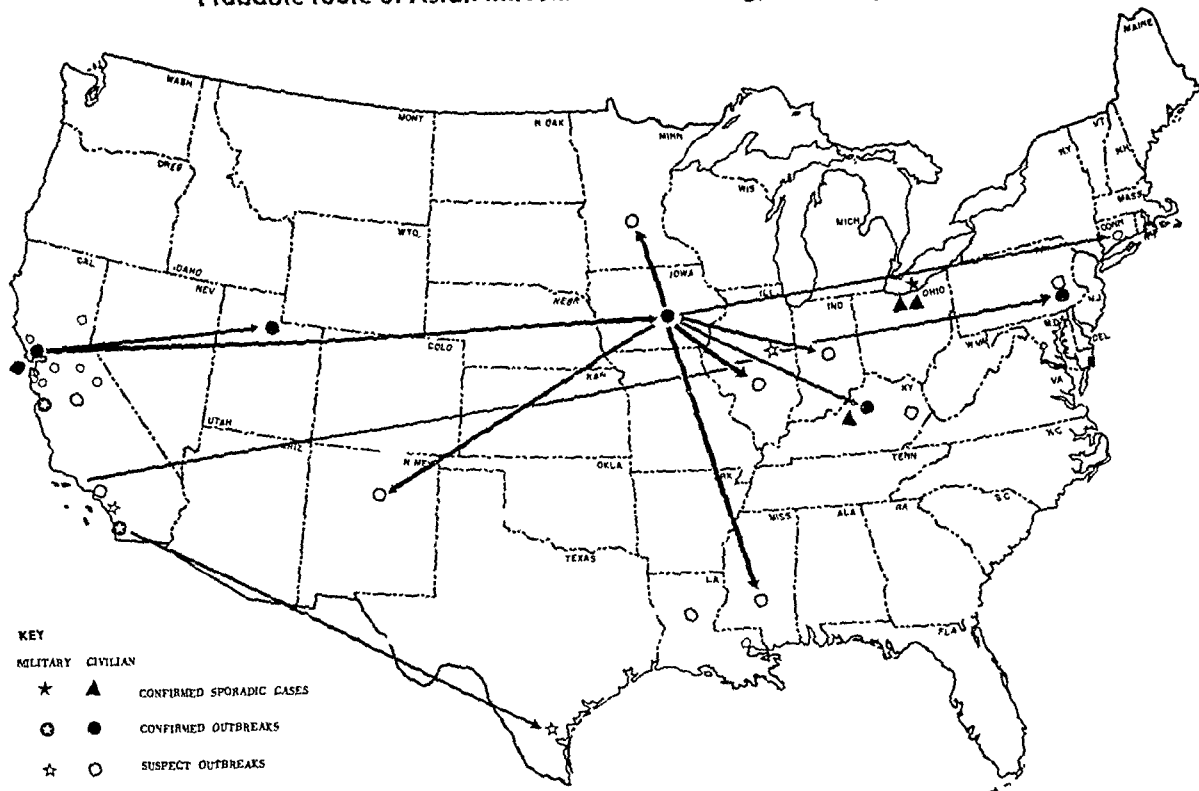

meeting of scientists present in Geneva to discuss the influenza situation. A useful exchange of information ensued. One of the incidental results of this meeting was international agreement that "Asian influenza" was both a descriptive and appropriate appellation for the contemporary manifestation of the ancient disease.

In mid-July two major policy decisions had to be made. Whether to recommend vaccination against influenza for civilians was one. Medically it was indicated, but the large quantities of vaccine that were needed had never been manufactured rapidly. The Surgeon General had decided to rely upon established physician-patient relationships for immunization. Except for protection of its own patients and employees, the Service did not plan purchases of vaccine. In these circumstances, could the manufacturers produce ample influenza vaccine? Would they shoulder the attendant risks?

From July 15 through July 19, the Surgeon General discussed the potential supply of influenza vaccine by telephone with each of the licensed manufacturers in turn. They appreciated the desirability, from the standpoint of public health, of immunizing as much as one-third of our population during the fall and winter. Given the forecasts of the epidemiologists and the plans being developed by the Public Health Service and the American Medical Association to meet an emergency, the manufacturers were willing to invest heavily in the production of influenza vaccine without financial assistance from the Government. Thus, a major administrative issue was resolved, and another significant contribution to the Nation's health was made by the industry.

The remaining unanswered question was whether to recommend that manufacturers continue making the monovalent vaccine then being produced solely to fulfill military contracts or to recommend production for civilian use of a polyvalent vaccine including the Asian strain. The opinion of the National Institutes of Health was that a polyvalent vaccine was preferable from an immunological standpoint, but the manufacturers were doubtful of their ability to produce large quantities of an effective polyvalent vaccine in the short time that remained. The National Institutes of Health conceded

Probable route of Asian influenza virus seeding, as of July 22, 1957.

that a monovalent vaccine would be preferable if the mortality associated with Asian influenza were to rise significantly. It seemed prudent as well as practical, therefore, to recommend a monovalent vaccine of the Asian strain for civilian use after the military needs had been met.

These were the crucial issues; the decisions were made by the Surgeon General. It was recognized also that these decisions should be "hedged" to reduce the adverse effects of rising influenza mortality, a possibility that could never be excluded. For this reason, the Division of Biologics Standards prepared a list of additional facilities that could produce influenza vaccine if the situation became more serious. It was believed that a mandatory allocation system for vaccine distribution and funds for purchase of vaccine and for public immunization clinics—all of which would also be necessary in the event of a grave emergency—could be obtained with relative speed if the situation ultimately warranted them.

On July 19 key officials of the Public Health Service discussed with the Under Secretary of

Health, Education, and Welfare the plans of the Service, the American Medical Association, the State health officials, and the vaccine manufacturers to cooperate in an effort to control or minimize the expected epidemic and to utilize the opportunities for research that could be foreseen.

On July 23 the World Health Organization sent a circular letter describing the influenza situation and suggesting that "countries with good facilities for large-scale vaccine production should, after satisfying their priority requirements, make available at the lowest economic price any surplus vaccine for priority groups in countries less favorably situated."

On July 25 the Division of General Health Services was designated the "focal point" in the Bureau of State Services for information about BSS influenza activities. A memorandum from the National Institutes of Health of the same date reported that vaccine manufacturers were obtaining higher yields in terms of CCA units as they gained experience with the Asian strain, an optimistic report with respect to potential vaccine production. A larger out-

put or higher potency, or both, than heretofore anticipated now seemed ultimately feasible.

On July 26 the chairman of the Committee on Control of Infectious Disease, American Academy of Pediatrics, met with officials of the Office of the Surgeon General to discuss vaccination against influenza. The Service agreed to provide the committee with all relevant information as it became available; the committee in turn agreed to develop technical advice for the guidance of pediatricians with respect to vaccination.

On July 30 the Surgeon General wrote to all State and Territorial health officers summarizing developments in the influenza situation and advising them of a forthcoming public announcement of the Service campaign to encourage maximum use of influenza vaccine. On August 1 a representative group of State directors of health education met with the Assistant to the Surgeon General for Information and other officials in Washington, D. C., to learn in detail of the plans the Service was making to encourage use of the vaccine when it became available. The Public Health Service expected a major share of this campaign to be in the hands of the States, with materials and national efforts provided by the Service.

On August 2 the Service issued a statement to the press to launch its campaign of public information and health education, and the Surgeon General again met with the press en masse. It was then possible to state that the influenza vaccine manufacturers expected to produce about 8 million cubic centimeters by mid-September, half of which would be available for civilian use.

A meeting of representatives of the Armed Forces, Veterans Administration, and the Public Health Service on August 2 was devoted principally to the question of influenza vaccine dosage. The judgment of the Office of the Surgeon General, after reviewing studies reported by military, civilian, and Service investigators, was that inoculation of 1 cc. of monovalent Asian influenza vaccine with a strength of 200 CCA units was the most effective and practical dosage to recommend.

On August 6 the Surgeon General reviewed the situation in a conference with the Secretary of Health, Education, and Welfare. On the

next day the Surgeon General and members of his immediate staff met with a committee representing the American Hospital Association to discuss the part hospitals could play in the care of the sick in the event of a serious epidemic.

Resources Readied for Epidemic

The Bureau of State Services reported on August 9 the first evidence of influenza occurring in epidemic proportions among the general population; previous outbreaks were among such "closed" groups as summer camps and naval vessels. On the same day the chief of the Civilian Health Requirements Unit completed an analysis of inventory increases by antibiotics manufacturers in anticipation of greater needs for treatment of complications of influenza. It was estimated that from 25 to 40 percent more antibiotics than usual would be on hand during the fall and that inventories could be further increased to from 40 to 100 percent above normal requirements within 30 to 60 days. The Surgeon General recommended to the Office of the Secretary of Commerce on August 9 that the export of Asian influenza vaccine be controlled while it remained in short supply.

On August 12, by individual letters, the Surgeon General asked the vaccine manufacturers to cooperate with the Public Health Service in the maintenance of a voluntary system of equitable interstate allocations of vaccine so long as it remained in short supply. Plans for this system had been developed by the Bureau of State Services. All manufacturers agreed to cooperate.

On August 13 the Surgeon General called a special meeting of all State and Territorial health officers to consider plans for the prevention and control of influenza. This action was taken pursuant to authority contained under section 312 of the Public Health Service Act. Preparations for the meeting on August 27-28 were a major item of business during the rest of the month.

On the following day, the Public Health Service met with more than 50 representatives of official, voluntary, and professional groups in the fields of health, education, and welfare to plan cooperative efforts to deal with the anticipated epidemic. Much of the smooth function-

ing of the professional groups involved during the months ahead and the lack of alarm or hysteria on the part of the public may be attributed to the immediate and continuing response of the national organizations represented at this meeting.

On August 14, also, the Surgeon General appeared before the Committee on Appropriations of the Senate to testify with respect to the President's request for additional funds for influenza activities. The committee had before it the Supplemental Appropriation Bill, 1958, which had been passed by the House of Representatives. As finally enacted, this bill provided \$800,000 in additional Public Health Service funds:

Production and distribution of diagnostic reagents -----	\$225,000
Influenza surveillance and laboratory services-----	385,000
Data collection and dissemination-----	80,000
Public information and health education----	110,000

In addition, transfer to influenza activities of \$275,000 previously appropriated for communicable disease control was authorized. Standby authority was also granted to transfer as much as \$2 million of emergency funds available to the President. Half was intended to defray the expense of calling several hundred Public Health Service reserve officers to active duty for loan to the States if the situation should worsen, and half was contemplated for purchase of medical supplies and equipment to be made available to States and communities in the event of a grave emergency.

On August 16 Public Health Service staff members met with representatives of the Army, the Committee on Disaster Studies of

the National Academy of Sciences-National Research Council, the University of Pennsylvania (Project Big Ben), and the American Medical Association to discuss proposals for a study of the effects of an influenza epidemic on community organization and functioning. This study was later conducted, primarily by the Service.

On August 21 the Surgeon General forwarded to the President's adviser on personnel his recommendations with respect to influenza immunization for Federal employees, which had been developed after consulting the Civil Service Commission, the Federal Personnel Council, and others. On August 23 the Bureau of State Services reported influenza among school children in Louisiana and Mississippi communities where schools open during the summer before the fall harvest season begins. This development was correctly believed to foreshadow similar effects after schools opened in other communities during the fall.

With the special conference on influenza of the Surgeon General with the State and Territorial health officials on August 27-28, the Asian influenza program of the Service moved from its developmental phase into its operational period. The relevant information had been received and evaluated, the alternatives had been established, the major decisions had been made, the individuals and groups involved had been alerted, the necessary control activities had been started in the Service and elsewhere, and a campaign of public information and education had begun. A comprehensive account of the subsequent activities, however, must await a later diarist.

Income Tax Regulations on Medical Deductions

Internal Revenue Regulations which govern deductions for medical and dental expense have been published in the Federal Register, December 14, 1957 (22 FR 10054). They are sections 1.213 and 1.213-1 of title 26 of the Internal Revenue Code of 1954.

Medical care is defined, a special rule for decedents is spelled out, and examples illustrative of the regulations are included.

Asian Influenza Surveillance

ALEXANDER D. LANGMUIR, M. D., MARIO PIZZI, M. D., WILLIAM Y. TROTTER, M. D.,
and FREDERICK L. DUNN, M.D.

IN MAY 1957 immediately after Dr. Maurice R. Hilleman, then with the Walter Reed Army Institute of Research, identified influenza viruses from the Hong Kong epidemic as "distinctly different from type A strains previously isolated from this country and Europe," steps were undertaken to meet the potential threat of an epidemic in the United States. It was anticipated that the new strain would be introduced into this country constantly by travelers returning from epidemic areas in the Far East. Single sporadic cases would probably be commonplace among such persons but difficult to recognize. Localized outbreaks among selected highly crowded population groups, particularly in the military forces, could also be expected, but no extensive epidemic spread was thought likely until fall.

All Epidemic Intelligence Service officers and all epidemiological personnel of the Communicable Disease Center, both at headquarters and in the field, were alerted for first priority duty in the investigation of influenza and influenza-like disease cases and outbreaks. During June few reports of cases were received, and these largely concerned personnel on military bases and ships. The first outbreaks appeared, surprisingly, among the crews of several destroyers at Newport Naval Station, R. I. In mid-June sharp outbreaks occurred among Navy recruits in San Diego and Army recruits at Fort Ord, Calif. At the end of June, an outbreak de-

veloped among high school girls at a conference on the campus of the University of California School of Veterinary Medicine at Davis, Calif. A nurse epidemiologist with the Communicable Disease Center participated with California State health officials in the investigation of this outbreak.

From June 28 to July 3 an outbreak of influenza appeared in Grinnell, Iowa, at a Westminster Fellowship Conference, which was attended by 1,680 delegates from more than 40 States and 10 foreign countries. A delegation of more than 100 students from California, at least one of whom had been exposed at the Davis conference, developed influenza en route and clearly introduced it to the other delegates. When this conference was disbanded, the infection was carried to all parts of the country. It was evident by this time, however, that the infection was being seeded in manifold ways.

In the early part of July, it became apparent that the routine morbidity reporting channels from the States to the National Office of Vital Statistics were not sufficient to handle the steadily increasing load of detailed reports. Accordingly, the Influenza Surveillance Unit was formally established in the Communicable Disease Center for the purpose of supplementing, but in no way replacing, the regularly established functions of the National Office of Vital Statistics. This surveillance unit was designed along lines similar to those initiated for the poliomyelitis surveillance reports in 1955. From its inception, the Influenza Surveillance Program was a joint undertaking of the Epidemiology Branch, with all of its Epidemic Intelligence Service officers and field personnel reporting continually and in detail, and the Respiratory Disease Unit of the Virus and Rick-

The authors are all with the Epidemiology Branch, Communicable Disease Center, Public Health Service, where Dr. Langmuir is branch chief and Dr. Pizzi, chief of the Surveillance Section. Drs. Trotter and Dunn are both in the Influenza Surveillance Unit.

etisia Section of the Laboratory Branch, with its rapidly expanding system of collaborating influenza diagnostic and reference laboratories.

The information from these extensive sources was consolidated with the large amount of data reported directly to the National Office of Vital Statistics from the States and military services. Lengthy reports were prepared weekly and distributed to all State health officers, State laboratory directors, State epidemiologists, and many others having interests or responsibility in the study and control of influenza. The first of these reports was published July 9, 1957.

Nationwide Spread

During July, Asian strain influenza was disseminated widely through the country. Outbreaks occurred chiefly in closed population groups such as children's camps and military installations. California camps were most heavily affected.

From July 11 to 18 an International Boy Scout Jamboree held at Valley Forge, Pa., was attended by a total of 53,000 Scouts and leaders from every State and from several foreign countries. At the beginning of the encampment there was evidence of influenza among Scouts from Sacramento, San Francisco, and Los Angeles, Calif., and from Louisiana and Puerto Rico. En route to the Jamboree, when the Scouts were in close contact for extended periods of time, many became ill. Laboratory studies have since demonstrated that their disease was Asian influenza. During the encampment many additional cases occurred among contacts of the originally involved groups, but no large epidemic developed in the camp. Three Epidemic Intelligence Service officers were stationed at Valley Forge to gather basic epidemiological and laboratory data. Additional cases occurred among Scouts on the way home, although again most of these were in the California and Louisiana contingents.

In the latter part of July, a number of new outbreaks occurred in children's camps throughout the country. Most of these could have been related either to the Boy Scout Jamboree or to other previously known outbreaks. There was very little evidence of community-

wide outbreaks affecting children and adults during July.

Influenza continued to appear in sporadic fashion during August. Certain incidents increased its spread and gave warning of future developments. Migrant workers, exchange students, Scouts, and others continued to disseminate the disease. However, during early August a major communitywide outbreak occurred in Tangipahoa Parish, La. It was readily apparent that this outbreak was related to the opening of summer school sessions in this rural area where children were required to work at the harvest later in the season. Spread from school children to other members of families was clearly demonstrated. Shortly afterward, nearby New Orleans began to experience the first major urban outbreak. These outbreaks were investigated by Dr. J. D. Martin of the Louisiana State Department of Health and two members of the Epidemic Intelligence Service. The belief that a nationwide epidemic might well begin with the general opening of public schools was further supported when several Mississippi counties also experienced communitywide outbreaks originating in schools that reopened in mid-August.

By late August there was no longer any doubt that a major nationwide influenza epidemic could be expected. For this reason, the Surgeon General of the Public Health Service called members of the Association of State and Territorial Health Officers to a special meeting on influenza to be held August 27 and 28. The purpose of this meeting was to review the influenza situation, to consider methods of control, and to coordinate all health activities to this end. One recommendation of the meeting resulted in a broadening and intensification of the CDC influenza surveillance activities. It was recommended that the States (a) adopt a program of epidemic reporting first by counties to the States and from them to the Public Health Service; (b) adopt a standard method of gathering and reporting information on outbreaks; and (c) sample absentee rates in selected schools and industries.

To facilitate this reporting by the States, the Communicable Disease Center designed a set of five forms. One of these was to be used for influenza reporting to the National Office

Figure 1. Weekly pneumonia and influenza deaths

in the United States through December 13, 1957.

of Vital Statistics and to the Center, and the others were to aid States in collecting data. On September 17 instructions and samples of each form were attached to the influenza surveillance report and sent to each State health officer, along with blanks for obtaining additional forms. Approximately 10,000 forms were mailed to the States to initiate their reporting systems, and an additional 45,000 have been sent to them since then in response to direct requests. Information gained from these forms has made it possible to estimate the geographic spread of the disease through the States.

In early September, as schools and colleges began to open, the number of influenza outbreaks increased greatly. Reports of new introductions of the disease by Mexican migrant laborers and foreign students continued. Communitywide epidemics spread further in the Mississippi-Louisiana region. Influenza vaccine was now being released in quantity, and weekly production and release figures were included in the surveillance report. In order to

measure the effects of influenza precisely, weekly analyses were prepared of excess mortality from influenza and pneumonia in 108 major United States cities (fig. 1). Shortly after the first release of vaccine, reports began to appear of nonallergic vaccine-associated deaths. Prompt investigation of these reports showed them to be poorly substantiated, and this fact was noted in the surveillance reports.

During the month of September, many Epidemic Intelligence Service officers participated in studies of local epidemics in order to determine further the behavior of the disease. Epidemic Intelligence Service officers also participated with the CDC Laboratory Branch in studies of vaccine effectiveness at Atlanta Federal Penitentiary and conducted studies of vaccine reactions in various population groups.

Early in October excess influenza and pneumonia mortality began to rise in the West South Central division, and by the end of the month the Nation as a whole was clearly experiencing increased deaths. Voluntary reporting

Figure 2. Localized outbreaks and countywide epidemics of Asian influenza, through October 27, 1957.

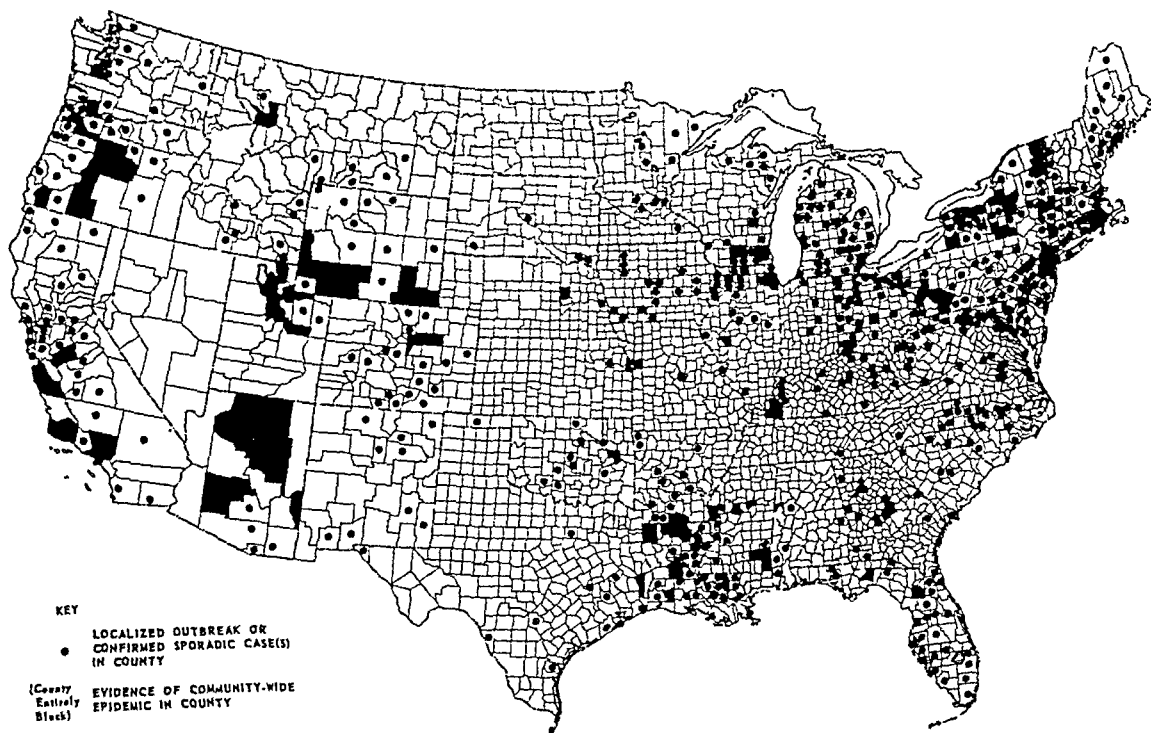

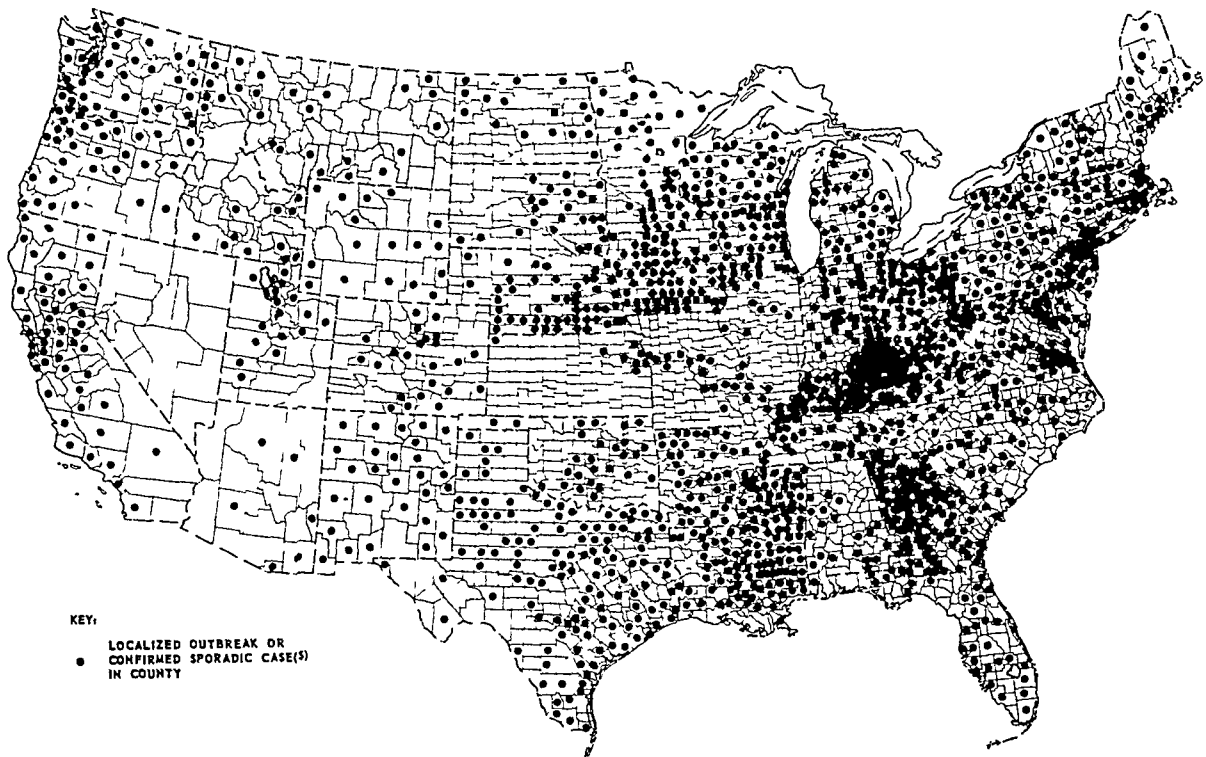

Figure 3. Geographic spread of Asian influenza, by county, through December 2, 1957.

of detailed influenza case histories resulted in a collection of valuable information regarding deaths and complications. This information was interpreted and published in the influenza surveillance reports to aid in treatment and stimulate further investigations. On October 15, through cooperation with certain corporations, it was possible to present industrial absentee data for 36 major United States cities. Several cities showed significantly increased absenteeism early in October, and most cities were affected before November. By this time influenza had reached at least 20 percent of the counties, and the county map (fig. 2) was beginning to lose its significance as an indicator of incidence. At this time effort to distinguish localized outbreaks from countywide epidemics was discontinued, and a new map was made to show simple geographic spread by counties (fig. 3).

A further measure of the epidemic was provided by the U. S. National Health Survey as preliminary data which the Influenza Surveillance Unit was permitted to publish. From all the available methods of measurement, it was

apparent that the epidemic was reaching a peak early in November, and by late November mortality, absenteeism, and new cases appeared to be on the decrease.

Despite the decline of the epidemic in late November 1957, the surveillance program continued in force because of the possibility of a second epidemic wave. The surveillance group continued its efforts to describe the epidemic and to define those areas in need of immediate or retrospective study.

Discussion

Although much data remain to be gathered, it is already possible to give a general picture of the 1957 epidemic as obtained through surveillance methods. Morbidity has been high, with clinical cases in approximately 25 percent of the population. But the mortality has been relatively low, in the range of 7,000 excess deaths from pneumonia and influenza. There has been no evident change in the severity of the cases with the progress of the epidemic, although it was possible to define certain special

risk groups such as pregnant women and persons with chronic cardiac and respiratory conditions. The present epidemic will probably result in more deaths than the A' influenza epidemic of 1953 and may eventually prove to be more severe than the A epidemic of 1943. However, it is in no way comparable to the pandemic of 1918 and is less severe as measured by mortality than nine epidemics that have occurred since 1920. There has been a rather

consistent pattern of initial involvement of high school children, followed by spread to elementary school children and adult populations. Industrial absenteeism increased a few days before excess mortality rose in a given urban community. Many deaths have occurred in the older age groups and in the debilitated. Staphylococcal pneumonia has been a prominent cause of death, although nonbacterial pneumonia has resulted in many deaths.

Sure Cures, 1918

"The present epidemic has given rise to the publication of numerous 'sure cures' and methods more or less plausible to the lay mind. The advocates of some of these have addressed long communications to Secretary McAdoo, to Surgeon General Blue, to the War Department, or other Government agencies. Hundreds of them have written to editors of newspapers. In general the suggestions fall into several groups.

"First comes the individual who has a specific remedy, the formula of which he is ready to give to the world for a price. One such writer reminds the Surgeon General of the million dollars that Congress has appropriated for combating influenza, and offers to sell his secret for 'a reasonable sum.'

"Next comes the person with the pseudo-scientific treatment, sometimes 'isotonic sea water,' sometimes 'ozono therapy,' and again

'harmonic vibrations.' One such writer, well known to the New York health authorities, addressed the Surgeon General from his present residence, the State Hospital for the Insane.

"The list might be continued, but the suggestions are largely variations and repetitions of what has already been cited.

"The United States Public Health Service urges the public to remember that there is as yet no specific cure for influenza, and that many of the alleged 'cures' and remedies now being recommended by neighbors, nostrum vendors, and others do more harm than good. The chief reliance must be on fresh air, nutritious food, plenty of water, cheerful surroundings, and good nursing. If any specific like a vaccine or serum is found to have value the Public Health Service will give the matter wide publicity."

Data on Acute Upper Respiratory Diseases

G. St.J. PERROTT and FORREST E. LINDER

IN AN unscheduled but propitious development, the U. S. National Health Survey is publishing current statistics which, in a tangential way, contribute notably to the aggregate of information on the influenza epidemic.

The data, the first to come from the new survey program, add several dimensions to the body of knowledge on communicable diseases. They come directly from a source we have not previously been able to tap on a national scale: the people affected by the diseases. They permit an association of incidence and prevalence with age and with two criteria of severity: bed disability and medical attendance. They provide a base for measuring the social and economic cost of the acute upper respiratory infections, including influenza.

The National Health Survey is not set up as an epidemic reporting system. Rather, it is designed to provide a continuing source of fundamental statistical information on the health of the American people in relation to important demographic, medical, social, and economic characteristics. This it will do in a series of reports which will begin to appear later in 1958. These reports will be based on data accumulated over one or more calendar quarters.

One part of the National Health Survey is a continuing household interview survey of a representative sample of the population, and it is

this project that has provided current statistics on acute upper respiratory diseases. The household interview phase has been under way nationwide since July 1, 1957.

Background

Household interviewing is continuous in order to increase accuracy, improve efficiency, and permit accumulation, over various periods of time, of data necessary for study of different health problems. Partly because budgetary considerations do not permit a sample sufficiently large to yield current estimates for items of low incidence or prevalence, it was not contemplated that tabulations by week or month would be made. However, when it appeared that in the fall of 1957 influenza-like diseases would reach a higher than usual level of frequency, the survey staff decided to investigate the possibility that the household interview data would yield useful current information about these diseases. The investigation took the form of a special tabulation of the weekly receipts of household interview schedules which showed acute upper respiratory diseases severe enough to cause 1 or more days of bed disability. (Roughly, the diseases included are International Statistical Classification categories 470-493 and 500 and also a special category for "virus" not otherwise specified.)

The household interviewing is conducted for the Public Health Service by the Bureau of the Census, which designs and selects the sample and processes the data in accordance with specifications established by the Service. The interviewing is done by trained lay interviewers, and the sample interviewed each week is repre-

Mr. Perrott is chief of the Public Health Service's Division of Public Health Methods, in which is located the U. S. National Health Survey. He was director of the national health survey conducted in 1935-36, the last previous effort to collect comprehensive health data nationwide. Dr. Linder is director of the U. S. National Health Survey.

risk groups such as pregnant women and persons with chronic cardiac and respiratory conditions. The present epidemic will probably result in more deaths than the A' influenza epidemic of 1953 and may eventually prove to be more severe than the A epidemic of 1943. However, it is in no way comparable to the pandemic of 1918 and is less severe as measured by mortality than nine epidemics that have occurred since 1920. There has been a rather

consistent pattern of initial involvement of high school children, followed by spread to elementary school children and adult populations. —*Public Health Reports, November 8, 1918.*

responding roughly to the 4 calendar months of July, August, September, and October.

Although the number of cases in the sample during July and August was quite small and the errors of sampling are therefore relatively high, the frequency distributions in table 2 point to an increase in the length of bed-stays during October as compared with earlier months. For example, the percentages of cases resulting in 3 or more days in bed were about 46 in July, 42 in August, 44 in September, and 56 in October.

For the whole of the 17-week period from June 30 to October 26 only about 1 case in 8 kept the person in bed for a week or more. This seems to confirm evidence from many other sources that the great majority of the cases during this period were mild.

Age Variations

Acute upper respiratory diseases causing 1 or more days of bed disability occurred more frequently among children and adolescents than among adults during the entire 4-month period. As shown in figure 2, the weekly rate of occurrence of new cases per 1,000 population was highest for the age group 5-19 years, somewhat lower for the age group 0-4 years, and lowest for the two age groups over 20 years old.

Although the average rate of occurrence of acute respiratory diseases for the 4-month period varied with age, little difference is found

Figure 2. Acute upper respiratory diseases¹ involving 1 or more days in bed: average number of new cases per week per 1,000 persons, by age group, United States, June 30-October 26, 1957.

¹ Including also influenza, pneumonia, and other similar conditions.

among the rates for the different age groups during July and August. The rates of occurrence for the four age groups are all quite low and similar in size (table 3). Although these rates may appear to vary inversely with age, care should be taken in inferring from these data any differences between the age groups for the July-August period, since these low rates are subject to relatively large sampling errors.

During October the age differences were marked. The average weekly rate of occurrence of new cases was highest for the age group 5-19 years, which had a weekly rate of 111 cases per 1,000 persons. The 0-4 year age group was next, with a weekly rate of 62 cases per 1,000 persons, while the two older age groups had the lowest rates, 41 for the age group 20-64 years and 21 for the age group 65 years and above. It should be noted that the age group

¹ Including also influenza, pneumonia, and other similar conditions.

tion of stay in bed to increase slightly as the epidemic progressed.

A rather startling aspect of these national figures on acute upper respiratory disease cases is the size of the numbers. Two things must be borne in mind in this connection. First, the statistics relate to the entire civilian population of the country, approximately 168 million in number; and, second, the estimates relate to some of the commonest ailments that mankind is heir to, as well as Asian influenza. In any winter, colds, sore throats, acute bronchitis, and similar conditions will probably affect a very sizable portion of the population, many of them more than once. Since these data from the National Health Survey are available for the first time this winter, there is no way of measuring the extent to which the number of respiratory cases was higher than usual. Nevertheless, it is an impressive fact that on approximately 104 million occa-

sions between June 30 and December 14 people took to their beds for a day or more because of illnesses of this type.

What fraction of these cases were influenza of the Asian strain? The National Health Survey household interviews yield no reliable data on this point. However, they provide the basis for interesting speculation on related matters. For example, if there is evidence from other sources that x percent of the upper respiratory disease cases during this period were Asian influenza, the survey results would suggest that by December 14 approximately $0.62x$ percent of the entire civilian population of the country had acquired some natural immunity to the Asian strain.

During this same 24-week period acute upper respiratory diseases accounted for about 363 million days of illness in bed. This total is equivalent to 994,000 person-years lost from usual activities, such as work, housekeeping, or school, and it does not include days of reduced activity when the person was incapacitated but did not go to bed. Using such data it would be possible on the basis of various plausible assumptions to make estimates of the monetary loss to the economy as a result of the upper respiratory diseases in an epidemic winter.

Length of Stay in Bed

The data on length of stay in bed tallied from the National Health Survey questionnaires provided a measure of the severity of cases of acute upper respiratory diseases. This information has to be treated with caution, however, since the bed stay for some of the cases had not terminated at the beginning of the interviewing week. In order to deal only with cases likely to be complete, analysis of length of stay in bed is restricted to cases that began during the second week before the week of interview. Since these cases began at least 7 days before the end of the 2-week period, cases requiring less than 7 days in bed were complete. The most that can be said about the length of time in bed for the other cases is that it was 7 days or more. Table 2 shows the frequency distribution of length of stay in bed for cases starting during 4 periods cor-

were similar and relatively low for each of the age groups. During October, however, substantial differences between the age groups occurred. For the age group 5–19 years, the average number of persons in bed each day was 51 per 1,000 persons, more than twice the figure for any of the other age groups. Almost one-half of the total number of bed-days of disability that occurred during October were experienced by persons in this age group, although, as was mentioned previously, the age group constitutes only one-quarter of the country's population.

Medical Attendance

In the household interviewing project of the National Health Survey, medically attended cases are those for which a doctor was consulted at home, at work, at the physician's office, in a clinic, or over the telephone.

Table 5 and figure 3 show, by date of occurrence, the proportion of cases that were medically attended among all new cases of upper respiratory conditions causing bed disability. During early and middle summer, when the frequency of these conditions was low, the proportion medically attended was around 60 to 70 percent. The proportion decreased to about 40 percent in late September and then turned upward to about 50 percent in October,

when the reported frequency of bed cases of acute respiratory conditions was at a peak.

For the entire period the proportion of medically attended cases was higher for the very young and for persons over age 65 years than for persons in the school or working ages. The proportion of cases medically attended decreased in September and increased in October within each age group as well as in the total population (table 6).

During the period of this report there were undoubtedly changes in the proportions of the various types of conditions reported under the broad category of acute upper respiratory conditions. This, together with changes in the volume of acute conditions, is probably reflected in the observed pattern of medical attendance. There are no comparable data for previous years, and the reason for the pattern of medical attendance seen here is a matter of conjecture.

5-19 years not only had the highest rate of occurrence but also accounted for a substantial proportion of the total number of cases. Although this age group represents only 25 percent of the total population of the country, it accounted for almost 50 percent of the total new cases that occurred during October.

The relationship between age and days spent in bed due to acute respiratory diseases presents a pattern similar to that shown by the relationship between rate of occurrence and

age. During the 4-month period the average number of persons in bed each day per 1,000 population was higher for children and adolescents than for adults (table 4). The age group 5-19 years had the highest rate, 17 persons in bed per day per 1,000 persons. The age group 0-4 years had a rate of 10 per 1,000 persons, while the age groups 20-64 and 65 and above had lower rates of 7 and 5, respectively.

During July and August the average numbers of persons in bed per day per 1,000 persons

Influenza Vaccine

JOSEPH E. SMADEL, M.D.

ANOTHER significant episode in the mass immunization of a large civilian population occurred during the Asian influenza epidemic. The acceptance of the current influenza vaccine program by laymen, physicians, and public health officials undoubtedly was favorably influenced by the highly successful campaigns for immunization against poliomyelitis. On the other hand, the development of Asian influenza vaccine and the production of almost 50 million ml. of this vaccine during the 7 months after the newly isolated viral agent was first brought to this country represent a remarkable feat which could have been accomplished only because of the enormous experience gained through the extensive study of influenza during the past two decades.

Dr. Thomas Francis and his associates of the Commission on Influenza of the Armed Forces Epidemiological Board have been outstanding leaders in the extended studies of influenza and in the development and demonstration of the efficacy of influenza vaccines (1). Following the pattern developed by the commission, the Army Medical Department and the Public Health Service created a series of influenza watch laboratories to assist in providing prompt and accurate information on the occurrence and spread of influenza. These watch laboratories have since been integrated with the World Health Organization's system which now encircles the globe (2).

Dr. Smadel is an associate director, National Institutes of Health, Bethesda, Md. This paper is based on comments at a symposium on Asian influenza held by the American College of Preventive Medicine and the health officers' section at the 1957 meeting of the American Public Health Association in Cleveland, Ohio.

A little-known experiment undertaken by American influenza investigators and the vaccine producers several years ago provided additional background for the work in 1957 with Asian influenza vaccine. In 1951 England experienced a moderately severe outbreak of influenza, which was considered a possible hazard to the United States. It was decided to determine how quickly the British virus could be imported and analyzed for antigenic composition, and incorporated into a vaccine, if it were found to be different from the earlier strains of influenza virus. Accordingly, at the height of the epidemic in Liverpool, British colleagues supplied a strain which was flown to the United States and promptly distributed to the laboratories at Walter Reed Army Institute of Research and the National Institute of Allergy and Infectious Diseases, Public Health Service. The institute, in turn, sent samples to the influenza vaccine manufacturers. The self-imposed problem of the various laboratories was to produce 1 liter of vaccine of acceptable potency, sterility, and safety in the shortest possible time. The two Government laboratories accomplished their task before the end of 3 weeks and the biologic houses shortly thereafter. The various workers recognized the portent of their achievement but realized that many factors had been in their favor and that similar success might not be regularly attained.

Development of Asian Influenza Vaccine

The present influenza vaccine program must make obeisance to each of the earlier developments described above. Using the watch laboratory organization, the Army Medical Department isolated the Asian influenza virus from patients in the Far East in late April.

Table 6. Acute upper respiratory diseases¹ involving 1 or more days in bed: percentage of cases which were medically attended among all new cases, by month of occurrence and age, United States, July–October 1957

Month	Age group

July and August-----	62	71	69	53	57
September-----	43	52	43	39	45
October-----	51	55	51	49	65

¹ Including also influenza, pneumonia, and other similar conditions.

² Figures for persons 65 and over are based on small numbers of cases in any given month and should be interpreted with caution.

It is possible that part of the increased volume of new cases in September is due to a normal seasonal increase in minor respiratory conditions for which medical attention is seldom sought. The October increase in the percentage of cases attended by a physician may result from the relatively heavier impact of influenza and an accompanying increase in severity, indicated by the longer stay in bed.

It is noteworthy that the lower proportion of cases which were medically attended in the latter half of the reporting period does not imply a decreased total volume of medical care. In the last 2 weeks of October there were about 12.4 million medically attended cases (table 5). This is greater than the number of medically attended cases during the entire 9 weeks of July and August.

The 12.4 million cases with medical consultation in the last half of October are cases for which the person went to bed. Estimates from other current National Health Survey data on acute respiratory diseases show that there were about half again as many cases with medical consultation but no bed disability. It can therefore be estimated that in this concentrated period of time approximately 18 million cases of acute upper respiratory conditions had medical attention, representing a tremendous volume of consultation and treatment provided by the medical profession.

Reliability of Data

Approximate sampling errors have been calculated for the estimated number of new cases each week. The sampling error varies somewhat from week to week, but 15 percent has been a typical relative error. This means that the estimated number of new cases for 2 weeks out of 3 should be within 15 percent of the figure that would be obtained from a complete enumeration, and it would be expected to be within 30 percent of a complete count in 19 out of 20 weeks.

Relative sampling errors for average number of persons in bed each day for any given week are of the same order of magnitude as for new cases. Estimates in adjacent weeks of average number of persons in bed are not entirely independent of one another, however, whereas each weekly estimate of new cases is independent of estimates for other weeks.

The sampling error for estimated proportion of persons with 3 or more days of bed disability also varies from week to week, but it is near 10 percent.

For monthly estimates, sampling errors are about 50 percent of those for the corresponding weekly figures. For estimates which refer to the entire 4-month period, sampling errors are about 25 percent of those for corresponding weekly data.

In considering reliability of items for which sampling errors have not been presented, two suggestions are offered. First, samples in any given week are quite small; consequently, a figure for any week or for the change from one particular week to another is subject to substantial sampling error and to fairly high risk of error from nonsampling sources. Second, it is desirable to focus attention on the general level or trend indicated by the collective evidence of several adjacent weeks, rather than on the level in any single week or the change from one week to the next. Similarly, samples for some subclasses shown are small, and there is advantage in considering the pattern reflected through several related subclasses.

The estimates of sampling error presented here do not allow for errors of response and nonreporting.

meeting the requirements. Moreover, 4,600,000 ml. of vaccine (total bulk volume) was released by the Division of Biologics Standards by September 5. Production increased dramatically, and by the end of October 42,600,000 ml. bulk vaccine had passed the tests performed concurrently by the vaccine manufacturers and by the Division of Biologics Standards.

Potency and Efficacy of Vaccine

Drawing on the fund of knowledge accumulated over the years from field trials by the Commission on Influenza, it was estimated in June that the effective dose of Asian strain vaccine would probably be not less than 200 chicken cell agglutination (CCA) units when administered subcutaneously to adult human beings. Because of the difficulties encountered during the early summer in obtaining high yields of Asian virus in embryonated eggs, it seemed unlikely that a vaccine containing more than 200 CCA units of Asian antigen could be produced. Hence, the potency of the new monovalent vaccine was set at 200 CCA units per milliliter (6a).

A series of studies undertaken during the summer by members of the commission, the Army Medical Department, the Communicable Disease Center, and the National Institute of Allergy and Infectious Diseases was designed to determine the effective dose of Asian antigen. Only those experiments bearing on three specific points will be mentioned. One is concerned with the level of antibody which developed in patients convalescent from Asian influenza. Another deals with the amount of viral antigen required to elicit a similar level of antibody in a vaccinated person. A third point is concerned with the level of antibody found in volunteers who were resistant to experimental challenge with Asian virus.

If some license is permitted in interpreting data of others, it may be stated that levels of hemagglutination inhibition antibodies of the order of a titer of 1:32 actual dilution of serum (or 1:128 final dilution of serum) were present in convalescent serums (3). Moreover, to induce a similar level in about 90 percent of persons inoculated with a single dose of vaccine given subcutaneously, 400-500 CCA units of

antigen were required (7), according to Keith E. Jensen of the Communicable Disease Center. Finally, appreciable resistance to challenge was displayed by those volunteers who had antibody levels of the order of 1:32. (In the tests of Bell and associates (7), 78 percent of the placebo controls developed signs of illness following challenge; 60 percent of vaccinated persons who failed to acquire detectable antibodies became ill; 43 percent of those with titers of 1:10 to 1:20 developed influenza; while only 25 percent of those who had titers of 1:40 or greater became ill.)

Such information as this, coupled with knowledge of the improved yields of virus from infected eggs and the increased facilities of the manufacturers, led to a recommendation in October that the potency of monovalent Asian influenza vaccine "be increased from 200 CCA units to 400 CCA units per milliliter as soon as feasible and not later than December 1, 1957" (6b). Current recommendations for the use of the vaccine appear on p. 130.

October 1957 saw the shift to the production of 400 CCA unit vaccine. Indeed, by November 1, two manufacturers had submitted to the Division of Biologics Standards for concurrent testing 13 lots with the 400 CCA unitage. As of November 12, 2 million ml. of 400 unit vaccine had been released by the division; 13 million ml. was available by December 12.

The report of Dr. Fred Davenport which appears in this issue (pp. 133-139) presents the available field information dealing with efficacy of Asian vaccine among military populations. In general, the data provide grounds for encouragement.

For many years, the influenza vaccines used in civilian and military populations have been of the polyvalent type, containing several strains of influenza A virus and one or more strains of influenza B virus. The formula for a polyvalent material which is now being produced for use during the latter part of the winter is as follows: influenza A, Asian strain—200 CCA; influenza A', PR 301 strain—100 CCA; influenza A, PR 8 strain—100 CCA; and influenza B, Great Lakes strain—100 CCA. The recommended basic course of immunization consists of 2 subcutaneous injections each

By mid-May the Department recognized that the virus was antigenically dissimilar from other influenza A viruses and that the American population was virtually without protective antibodies against the new strain (3). Simultaneously, investigators in other countries made comparable observations. Numerous other investigators in university, governmental, and industrial laboratories in the United States began their studies on the Asian virus during the last week of May. In the meantime, WHO influenza detection centers throughout Asia, the Western Pacific, Australia, and the Middle East noted and reported the rapid spread of influenza from Hong Kong. It soon became apparent that the new virus was highly contagious, provoking large epidemics affecting up to 20 percent of the general population in one area after another, and in certain selected groups involving 60-70 percent of the population. Fortunately, the mortality remained low as the disease continued its sweep (4).

As a result of intensive work in the commercial laboratories, the first experimental lots of Asian monovalent vaccine were available before mid-June and were promptly placed under assay in volunteers by personnel of the Commission on Influenza, the Army, and the Public Health Service. It is worth noting that the first cases of Asian influenza were diagnosed in the continental United States during the first week of June (5a).

The military services, during the latter part of June, provided a most important stimulus to the commercial production of vaccine by inviting bids for 2,650,000 ml. of monovalent Asian vaccine. At about the same time, the Surgeon General of the Public Health Service informed the manufacturers that he anticipated the need for large amounts of influenza vaccine for use by the civilian population during the coming fall and winter. With these demonstrations of active interest in a vaccine prepared against the newly isolated Asian influenza virus, the manufacturers that had produced influenza vaccine in previous years offered to make a strenuous effort to meet the demands created by the anticipated epidemic. These manufacturers undertook this commitment, which involved considerable financial risk, without government subsidy.

Vaccine Dosages

The Public Health Service recommends the following dosages of Asian influenza vaccine:

For those who have not been vaccinated, subcutaneous injection of 1.0 cc. of the 400 CCA unit strength Asian influenza vaccine currently being produced.

For those who have received 0.1 cc. intracutaneously or 1.0 cc. subcutaneously of the 200 CCA unit vaccine previously produced and for those individuals at special risk (pregnant women, older persons, and those with chronic respiratory or cardiac disease), a second 1.0 cc. subcutaneous injection of 200 CCA vaccine is recommended. Physicians may also wish to recommend a second injection for other patients. If the 400 CCA unit strength vaccine is available, 0.5 cc. should be given. The second dose should be received not less than 2 weeks after the first.

For children, the recommendation of the American Academy of Pediatrics is: For children under 5 years of age, 0.1 cc. intracutaneously or subcutaneously, repeated after 1 to 2 weeks; for children from 5 to 12 years of age, 0.5 cc. subcutaneously, repeated after an interval of 1 to 2 weeks; for children over age 12, the adult dosage.

The summer months were devoted to solving technical problems such as (a) increasing the yield of virus growing in embryonated eggs, (b) developing methods for assaying potency which would circumvent the time-consuming procedures previously employed, (c) determining the immunogenicity of the vaccine in man, (d) training new technical teams in the pharmaceutical houses and renovating old facilities or constructing new, and (e) arranging for unprecedented quantities of fertile hens' eggs.

By mid-August, two manufacturers had produced a total of 500,000 ml. of monovalent Asian vaccine and obtained its release by the Division of Biologics Standards of the Public Health Service. Progress thereafter was rapid. Before the end of the first week in September, each of the six companies manufacturing the vaccine had produced one or more lots

Role of the Commission on Influenza

FRED M. DAVENPORT, M.D.

SINCE 1940 the Commission on Influenza of the Armed Forces Epidemiological Board has been continuously engaged in investigations of influenza and has given special attention to the development of an effective method for prevention of this disease. The results of controlled field trials in 1943 and 1945 convincingly demonstrated the effectiveness of vaccination against influenza A and influenza B. Vaccination studies in 1947 showed with equal authority that vaccines of limited antigenic coverage were ineffective against the A' variants prevalent that year and gave an unequivocal answer to the question, Are antigenic differences detected by laboratory methods of practical importance for immunization?

Despite the difficulty of conducting field trials in years of low influenza incidence, the results of studies carried out between 1949 and the spring of 1957 clearly demonstrated how to cope with the phenomenon of sudden major antigenic shifting. Vaccines containing the A' variant were repeatedly shown to be effective against influenza A' (1). During this period few studies on vaccine effectiveness were carried out under auspices other than those of the Commission on Influenza.

The vaccine trials have been only one of the commission's major functions. A chain of laboratories was established in 1942. These are

still maintained to serve as listening posts for the early detection of influenza, to document its spread, and to provide virus samples to a central strain study center for antigenic analysis. This system has been continuously productive of valuable epidemiological information. For example, in 1943 scattered local outbreaks of influenza A were identified in the spring and early summer before the extensive epidemic began in November of that year. In 1945, when the system was extended to include observations in most of the areas where the U. S. Army was engaged, a series of small outbreaks of influenza B, extending from March to the epidemic buildup in November and December, was traced in the United States and Alaska, in the Pacific and Caribbean theaters, and in Australia and South America. These observations revealed a year-long widespread prevalence of influenza B with a sharp fall and winter epidemic peak. The Army laboratories, and later the World Health Organization, have continued and expanded this activity into a vast network so that by now the point-to-point spread of influenza can be rapidly and accurately followed, and the data can be viewed in historical perspective. The summer occurrence of Asian influenza was therefore not a new finding and in itself did not herald catastrophe.

Development of Influenza Vaccines

In addition to the laboratory observations, since 1942 studies made by the Commission on Influenza of the dimensions of antigenic variation of influenza viruses and their significance for immunity induced by vaccination or acquired by repeated infection have led to the recognition that the common antigenic components of influenza viruses provide a degree of cross resistance. The objective for prevention

Dr. Davenport, of the virus laboratory, department of epidemiology, University of Michigan School of Public Health, Ann Arbor, Mich., is director of the Commission on Influenza, Armed Forces Epidemiological Board. This article is based on a paper given at a symposium on Asian influenza held by the American College of Preventive Medicine and the health officers' section at the 1957 meeting of the American Public Health Association.

of 1.0 ml., the second following the first by not less than 2 weeks.

Future

While the record to date for developing and producing Asian vaccine has been truly amazing, it would be foolhardy to assume that it will be possible to do as well or better the next time the country is confronted with a severe epidemic caused by an unfamiliar strain of influenza virus. There was an interval of almost 6 months between the time the first strain of Asian virus reached a research laboratory in the United States and the time at which the weekly pneumonia and influenza deaths increased above the "epidemic threshold" in the 108 cities which are under surveillance by the Communicable Disease Center (5b).

Suppose the next widespread occurrence of influenza begins in North America or arrives here promptly and reaches epidemic proportions within a month or so? The measures which were successful in this epidemic did not provide any useful quantity of vaccine during the first 2 months after the virus seed reached the manufacturers. I think it is obvious that the search must continue for means of rapidly increasing the resistance of populations to epidemic influenza.

Recognition of this fact was one of the reasons the Surgeon General of the Public Health

Service, on the recommendation of the Association of State and Territorial Health Officers, established an Advisory Committee on Influenza Research. This committee was asked, among other things, to consider and advise the Surgeon General on what further research might be undertaken to strengthen influenza control in the future and to suggest where such research might most profitably be done.

Vaccines, 1919

"The only way in which we are to secure promptly acceptable evidence of the value of a bacterial vaccine is by the vaccination of only a portion of the individuals in a large group, holding the remainder as controls; age, sex, and conditions of exposure being the same in the two groups.

"On the other hand, a vaccine should not be condemned unless controlled as just indicated, and unless it has failed to show protec-

tive value when sufficient time has elapsed after the inoculation to make it reasonably likely that any immunity which may develop will have had an opportunity to do so.

"A large number of vaccines have been used, some made from the influenza bacillus alone, others from this in conjunction with pneumococci, staphylococci, and streptococci, and in various combinations; the failure of one does not necessarily mean the uselessness of others."

—G. W. McCoy, Director, Hygienic Laboratory, Public Health Service,
Public Health Reports, May 30, 1919.

The number of deaths from pneumonia occurring after influenza increased dramatically, but neither the case fatality rate nor the age distribution of pneumonia patients was different from other years—again there was no evidence of increased virulence of Asian influenza. There was just much more influenza, many more pneumonias, and hence a greater number of fatal cases of these diseases. In a careful study of about 50 fatal cases, it was found that approximately one-half showed evidence of staphylococcal pneumonia, while death in the remainder could largely be attributed either to overwhelming infection by organisms readily responding to early conventional treatment or to less intense infections in persons who had chronic disease involving vital organs. A small proportion of fatal cases were associated with infection in the last trimester of pregnancy. In a small number of cases the cause of death was recorded as hemorrhagic pneumonia, apparently without detectable secondary bacterial invasion. However, it was stressed that the pneumonia cases generally responded well to antibiotics.

The results of these field investigations were reported to the Surgeons General of the three armed services and to the Surgeon General of the Public Health Service. These reports served as timely and precise information to dispel rumor, to establish the pattern of the behavior of Asian influenza, and to forecast what might be encountered in the United States during the fall and winter of 1957-58.

Virus Strains of Asian Influenza

As time permitted, the question of the antigenic relationship of Asian strains to strains prevalent in former years was explored by studies carried out in the virus laboratory of the University of Michigan's School of Public Health at Ann Arbor. The information gained from the field trips and from other sources indicated that Asian influenza followed the familiar pattern of incidence by age outlined in former reports on the attack rate of influenza caused by strains similar to those of swine influenza (1918), by A strains (1943), and by A' strains prevalent since 1947. The incidence of Asian influenza was highest in childhood and progressively lower in older age groups. The

most plausible thesis yet presented to explain this phenomenon is that relative immunity in older persons is conferred not by highly strain-specific antibody but by a composite of antibodies built up by repeated exposure to other antigenic variants of influenza A (2). In consequence, then, persons having a composite antibody have a broad immunity to influenza even though their serums may show by conventional methods little or no hemagglutination inhibition (HI) antibody against the prevailing virus. To develop a composite antibody and a broad immunity by vaccination with several selected strains of virus has become one of the goals of the Commission on Influenza. It was important, therefore, to discover whether the relative resistance of older persons to Asian influenza could be correlated with detectable antibody.

The first significant report on the demonstration of antibody in the serums of normal humans came through Dr. Mulder from Leiden, Holland, who found respectable concentrations of antibody against Asian virus in the serums of a small proportion of persons 70-80 or more years of age (personal communication). This finding was promptly confirmed in Ann Arbor and elsewhere with serums obtained locally and, subsequently, with serums received from Dr. Mulder. Moreover, at Ann Arbor it was shown with pools of serums collected by 2-year age intervals that antibody detectable by complement fixation with Asian virus antigen was not present in persons below the age of 30 years but was usually present at low levels in those above 30. In addition, by hemagglutination inhibition, using special treatment of serums and antigen, low levels of antibody were frequently found at ages corresponding to those at which high levels of A', A, and swine influenza virus antibodies are regularly present. There could be no doubt, then, that Asian virus was, antigenically speaking, not a completely "newe acqayantance."

This opinion was confirmed by observing the antibody response of four age groups to Asian virus vaccine given as 250 CCA units in 1 ml. subcutaneously (table 1). For this presentation, antibody levels are expressed as the geometric mean value of the groups studied, using final dilutions of serums for the calculations.

of influenza by vaccination has become the development of a vaccine of broad effectiveness containing representative strains of the major antigenic families of influenza viruses (2). It was natural then for the commission to be deeply interested and involved when Dr. Maurice R. Hilleman, then chief of the Respiratory Disease Division, Walter Reed Army Institute of Research, reported that another major antigenic shift had occurred and that the new viruses were responsible for the severe epidemics reported from the Orient in April and May of 1957 (3). Promptly, a number of steps were taken by the commission to assess the significance of these events.

On the basis of the first epidemiological and immunological information available, it seemed quite unlikely that vaccines used in former years would provide optimal protection against Asian influenza. In a series of conferences held first with military and later with civilian health authorities, a program was developed for primary immunization against the new antigenic variant, using monovalent vaccines of the highest potency obtainable—at that time 200 chicken cell agglutination (CCA) units—to be followed in the military after a suitable interval by a booster dose of polyvalent vaccine containing the old as well as the new strains. The negotiations and the placing of a large order for vaccine by the military gave an essential impetus to vaccine production. Later, as part of the unprecedented effort directed by the Public Health Service in preparation for the current epidemic of Asian influenza in the civilian population, production of influenza vaccine was greatly expanded. Plans for effective use of vaccine were formulated, and successful methods were put into operation to maintain detailed surveillance of the spread and character of the influenza epidemic. These important developments comprise the most vigorous effort ever made to protect a population against influenza—the last great plague of mankind.

Influenza Surveys

In keeping with the traditions of the Armed Forces Epidemiological Board and its commissions, I made a reconnaissance early in June in Australia, the Philippines, Japan, and the

Hawaiian Islands to gain first-hand information from virologists, clinicians, and military and public health agencies about the impact of Asian influenza in these areas. At that time, when rumor was rife but facts were difficult to acquire, it was found that the disease was widespread although clinically mild. The influence of crowding on the incidence of Asian influenza was quite apparent. The influenza attack rate in Navy personnel stationed on ships was clearly higher than in those based on shore, who, like the personnel of the Army and the Air Force, had the benefit of a larger number of cubic feet of air space per man. The incidence of influenza was obviously higher in the lower socioeconomic groups of the countries visited, those groups who lived in closer proximity to each other than did their more fortunate neighbors. Moreover, it was learned that Australia had been seeded with influenza early in its winter season; yet no catastrophic epidemic had resulted. The influence, then, of cultural factors on the severity of epidemic influenza was again shown.

The fatalities in the Orient, reported in the press without appraisal, were found to be concentrated in the very young and in the old-age groups. Moreover, the attack rate by age followed the familiar pattern, being highest in childhood and becoming progressively lower thereafter. Finally, considering the number of deaths reported and taking into account the number of persons ill, it was apparent that Asian influenza was not a particularly virulent form of infection. It was reassuring to learn that, despite an attack rate of about 30 percent, there had been no disruption of essential activities in either civilian or military communities.

Later, in August 1957, a field study was established in Santiago, Chile, to observe the effects of Asian influenza in a country which ordinarily has a high incidence of pneumonia during its winter season. Dr. Harold B. Houser was the field director of this special study group, and the members were selected from personnel of the Commission on Influenza, the Commission on Acute Respiratory Disease, and the Commission on Streptococcal Diseases, Armed Forces Epidemiological Board. Chilean investigators collaborated most effectively in this effort.

Serums were collected before and 2 weeks after subcutaneous vaccination with 1 ml. of vaccine. Clearly, the frequency of antibody increase and the amount of antibody stimulated by vaccine of 100 to 250 CCA units were irregular and of low order. These poor results are like those observed in former studies when strains of influenza virus were given to persons who had not previously been exposed to these strains (4). With vaccines of 400 CCA units and above, antibody increase was more uniform and the postvaccination levels were, in general, higher. These levels approach those found in the earliest successful field trials of vaccination carried out by the Commission on Influenza but are lower than the levels observed in recent years with vaccines of higher potency. The data also imply that doubling the dose of virus from 400 to 800 CCA units does not commensurately increase the frequency or amount of antibody increase. Several members of the commission supervised the administration of most of these vaccines, collected the serums, and shipped them to the virus laboratory at Ann Arbor so that comparisons could be made under uniform conditions. The data were available by late August

1957 and were widely circulated. They supply one basis for the recent increase in potency of monovalent vaccine from 200 to 400 CCA units per dose.

Effectiveness of Asian Influenza Vaccines

The Commission on Influenza has now obtained the first specific information regarding the effectiveness of vaccines of varied potency against the current epidemic of Asian influenza. They indicate that protection is increased as the dose of virus is increased.

The studies summarized in table 2 were begun as soon as influenza vaccines of desired potency could be obtained in sufficient quantity. On July 26, 1957, Dr. J. O. Culver and Dr. Edwin H. Lennette began to inoculate 40 percent of the recruits newly assigned to training companies at Fort Ord, Calif., with monovalent Asian influenza virus vaccine containing 250 CCA units per milliliter. One milliliter of vaccine was given subcutaneously in this and in the following studies. Sixty percent of the men in each company received a placebo injection of formalinized saline. At the time the

Children.....	² < 32	3/25
Recruits.....	< 32	2/23
Middle-aged persons.....	32	11/25
Persons over 80 years of age....	281.6	11/14

¹ Numerator—number of persons showing antibody increase even when an increase was found only in the next highest dilution of serums; denominator—number of persons studied.

² Geometric mean postvaccination hemagglutination inhibition antibody titers. Prevacination titers were less than 32.

Children and military recruits showed no antibody increase as measured with the ferret-mouse-egg line of Japan 305 strain; middle-aged adults showed as a group antibody increase from less than 32 to 32. Eleven of the twenty-five subjects studied showed some antibody increase. However, in a group of 14 persons 80 or more years of age, antibody rose after administration of the same vaccine from less than 32 to 281.6, and 11 of the 14 subjects showed antibody rise. Four of fifteen other senior citizens showed a rise in influenza antibody when vaccinated with older strains.

In contradistinction to earlier explanations by other investigators, the accumulating epidemiological and immunological data strongly indicate that the high attack rate and ease of spread of Asian influenza do not reflect a total lack of immunity in the population. Rather, the data suggest that the capacity for rapid spread at high attack rates may be unrelated to the antigenic structure of the prevailing virus. This was certainly true when the A' strains emerged in 1946-47.

From the serologic findings in the current experience, correlations can be made between the resistance of very old persons to influenza and the presence of antibody that reacts with strains of Asian influenza. Dr. Mulder first suggested that the virus involved in the pandemic of 1890 was closely related to Asian strains, and our findings lend support to his hypothesis. More importantly, they suggest that antigenic variation among influenza vi-

ruses has finite limits and that antigens formerly prominent are bound to be repeated as major antigenic components. This view supports the concept that ultimately a polyvalent composite vaccine can be given which will induce a broad immunity against influenza, an immunity that will no longer be jeopardized by sudden and unexpected antigenic shifting. The alternative is to pursue endlessly the futile course of trying with present methods to prepare a monovalent specific vaccine each spring to combat the unknown strain of influenza virus anticipated for the fall.

The Commission on Influenza was also concerned with defining the antibody response of humans to monovalent vaccines containing Asian virus because past experience had indicated that, while vaccination with the new strain was desirable for optimal protection, one could expect that antibody response and hence protection would not be optimal using the 200 CCA dose that was made the standard early in the summer. In brief, it seemed unlikely that an antigenic change in the strain would necessarily change immunological principles. Hence, owing to the increased yield of virus in eggs, as soon as vaccines could be prepared at higher unitage, studies were aimed at defining the dose-antibody response relationship in man to the virus of Asian influenza. The results of tests using vaccines prepared by 3 different pharmaceutical concerns by 3 different methods of manufacture are tabulated below.

Titer, by virus dose (units)	Frequency of antibody rise ¹

NOTE CCA=chicken cell agglutination.

Comdr. B. F. Gundelfinger, Jr. Vaccination of recruits was carried out on August 10, 1957, using two vaccines and a control material. The first vaccine contained 200 CCA units per milliliter of Japan 305 strain of influenza virus. The second vaccine, the Armed Forces 1956-57 polyvalent influenza vaccine, did not contain an Asian strain. This vaccine was composed of 250 CCA units each of swine, FM1, and Great Lakes strains. Thirty percent of the study population received monovalent vaccine, 30 percent received polyvalent vaccine, and 40 percent received placebo. Illness clinically diagnosed as influenza appeared at Great Lakes in epidemic proportions during the week ending October 5 and continued through the week ending October 19. In fact, the admission rate for the week ending October 12 was higher than the admission rate for any week during the past 8 years.

The average admission rate of recruits for the 3 weeks was 162.0 per 1,000 in the placebo-inoculated group, 39.8 in the group receiving monovalent Asian virus vaccine, and 92.1 in the group receiving 1956-57 polyvalent vaccine. In this short interval the effectiveness of the monovalent vaccine was approximately 75 percent and of the 1956-57 polyvalent vaccine about 43 percent. If the apparent protective effect of the polyvalent vaccine is substantiated when the studies are completed, this information will add to the data now at hand demonstrating important antigenic relationships between the Asian strains and other strains of influenza virus isolated in former years. This result encourages the outlook for a practical composite vaccine of broad coverage.

Although the studies reported in table 2 are incomplete, the trends shown are sufficiently distinct to indicate the final effects of vaccination with vaccines of various potencies. These effects should be increased when laboratory studies identify and remove from the study cases of illness caused by other respiratory disease agents which are so common in recruits. Results of the studies emphasize, too, that vaccine of 200 CCA units gives somewhat less than optimal results, but that the effectiveness of vaccination can be increased by giving higher doses of virus.

Summary

This brief account of the role of the Commission on Influenza of the Armed Forces Epidemiological Board in studies of the epidemiology and prevention of influenza outlines the accomplishments of a group which has been working continuously and closely with the military since 1940 in the study of influenza as a disease problem. Largely by the efforts of this commission, the effectiveness of vaccination as a practical measure in preventing influenza has been firmly established, and the results of the commission's studies have given direction to the present effort to minimize the effects of epidemic Asian influenza.

Field studies conducted outside the United States on the incidence of Asian influenza in different age groups clearly showed the relative immunity of the older segments of the population to this disease. Laboratory studies carried out in Ann Arbor, Mich., and elsewhere have begun more clearly to define the antigenic relationships of current strains of influenza virus to older viruses and to demonstrate the antibody foundation of the relative immunity of the older age group. Field studies abroad also provided clinical, virologic, bacteriological, and pathological information on Asian influenza and its complications.

Finally, the results of the vaccine trials have provided the first specific evidence of clinical effectiveness of vaccine against the current epidemic of Asian influenza and have shown the value of increased dosages in providing more optimal protection against this disease.

study was begun, Asian influenza was already prevalent at Fort Ord, and most of the patients with respiratory illness could not be admitted to the station hospital. Therefore, the effectiveness of the vaccine was measured by comparing the rate of dispensary visits for respiratory disease observed in the vaccinated and the rate in the unvaccinated populations. Cases of influenza occurring within 10 days after administration of vaccine or placebo were not considered in the evaluation because influenza was prevalent on the post at the time of vaccinating the recruits, and significant antibody increase would not be expected until 10 days after vaccination. For the period August 5-26 a rate of 21.8 cases of influenza per 1,000 recruits was found in the vaccinated group and a rate of 37.9 per 1,000 in the unvaccinated group, an estimated effectiveness of 42 percent.

At Lowry Air Force Base, Colo., Dr. Gordon Meiklejohn and his associates began their studies on July 29, 1957. Within 2 days, 775 airmen had received monovalent vaccine containing 200 CCA units per milliliter of an Asian strain of influenza isolated in Formosa. A placebo injection of formalinized saline was given to 806 airmen. The preparations were alternated within military units so that approximately 50 percent of the persons in each unit received virus vaccine and 50 percent, control material.

On September 23, a second study was established using three different influenza virus vaccines and a placebo preparation. In this study, 25 percent of the members of each unit received one of the following: (a) monovalent vaccine containing 400 CCA units of Japan 305 strain, (b) polyvalent vaccine containing 400 CCA units of Japan 305, 200 CCA units each of swine (A-1931) and Great Lakes (B-1954), and 100 CCA units each of PR 8 (A-1934) and PR 301 (A'-1954), (c) influenza B vaccine containing 400 CCA units of the Great Lakes strain of 1954, or (d) formalinized saline. About 600 persons received each preparation. The concentration of Asian virus in these vaccines is probably higher than in the vaccines used at Fort Ord, since independent measurements have indicated that the commercial laboratory which, upon request, prepared the vaccine for Lowry Air Force Base usually

underestimated the virus content of their product.

At the end of July, when vaccination was initially carried out at Lowry Air Force Base, there was no evidence of the presence of influenza, but the disease appeared in the third week of September. Dr. Meiklejohn and his associates have analyzed the admissions to the hospital for acute respiratory disease from September 16 to October 27 for those vaccinated with 200 CCA units of an Asian strain of influenza virus and for the control group. The approximate protective effect was 61 percent. In the second study, no significant differences in the occurrence of respiratory infections were observed between the groups inoculated on September 23 during the first 10 days after vaccination. However, in the subsequent period the approximate protective effect of vaccines containing 400 CCA units of Asian virus appears to be 67 percent. Note the apparent increased effectiveness of the more potent vaccines containing 400 CCA units (table 2).

At Fort Dix, N. J., Dr. Harry Rose and his associates began vaccination of recruits on August 1, 1957, using two different vaccines. One contained 200 CCA units of Japan 305 strain per milliliter and the other, 750 CCA units. Companies of recruits arriving at Fort Dix were divided into thirds by roster, and each group received either 200 CCA units of virus, 750 CCA units of virus, or formalinized saline. The vaccination program was completed on September 6. A sharp outbreak of Asian influenza occurred at the end of September. Dr. Rose has tabulated the hospital admission rates for respiratory disease in each vaccine group from September 29 through October 20. The rate per 1,000 in the control group was 76.1; in those receiving vaccine containing 200 CCA units, 33.2; and in those receiving 750 CCA units, 17.4. The estimated effectiveness of the 200 unit vaccine was 57 percent and of the 750 unit vaccine, 77 percent. In this study, as in Dr. Meiklejohn's, the increased effectiveness of higher doses of virus for vaccination is clearly shown.

The Surgeon General of the U. S. Navy has provided information about the results of studies carried out at Great Lakes Naval Training Center, Ill., under the direction of Lt.

Laboratory Support Program

The pattern of providing financial and other types of assistance to laboratories, principally those of official health agencies, as later discussed, had been established earlier in the poliomyelitis diagnostic field. Anticipating a need for specific diagnosis of influenza, in order that accurate estimates of attack rates could be obtained, a basically similar program was planned by the Communicable Disease Center. This as executed consists of reimbursing official health agency laboratories for contractual services, which include establishing and maintaining facilities for isolating and typing influenza virus, maintaining serologic procedures, and reporting results of laboratory study of cases to the Center.

Certain academic or institutional laboratories have essentially similar types of contracts to provide this service to States, or to serve in a resource capacity in the evaluation of materials, procedures, or skills.

The facilities thus established are intended to perform functions expected to provide better intelligence on influenza than might otherwise be expected. The services of the laboratories will include examination of clinical materials from index cases of respiratory diseases in order that local influenza outbreaks may be early recognized. Since much influenza-like disease is prevalent, the workload involved in the early detection of influenza has been substantial. Additionally, the laboratories participating in the program are directing special efforts toward obtaining isolates, either viral or bacterial, from persons with severe influenza infections, and similar material from fatal cases that come to autopsy. All cooperating laboratories are participating in a technical evaluation of procedures and skills so that appraisal of the value of the different diagnostic techniques can be made and so that some estimate of the range in results of tests in the various laboratories can be determined.

Earlier Observations

Variations among type A influenza viruses have been studied for many years but significant antigenic differences and relationships have been most clearly demonstrated by field trials of vaccine. In the laboratory, results of

antigenic comparisons of the different strains with cross-tests utilizing various antisera have provided detailed information about shared antigenic components. It has also been possible to show that periods of prevalence for virus strains with particular major antigens are reflected in patterns of antibody titers in human sera from various age groups. These developments have been reviewed elsewhere (4). It was evident from these past studies that a new set of type A variants of the influenza virus could be expected.

One of the lessons learned during the past 15 years was that influenza vaccines could be relied upon to be effective in reducing the incidence of the disease only when the vaccine formula included strains representative of the prevalent set of viruses. Recognizing this, the World Health Organization established strain study centers with many strategically located surveillance laboratories with the view toward rapid identification of virus isolates from each new outbreak. The viruses thus obtained in Singapore, Formosa, and Japan during May 1957 were strikingly different from previous type A strains. The incidence of antibody against these viruses in human sera was extremely low. The expected new set of viruses had appeared and promised to spread uninhibited throughout the world population. Anticipating this, the WHO program participants and responsible military and Public Health Service officials were alerted, and within a week prototype strains were sent to vaccine manufacturers for pilot studies and to the collaborating laboratories so that each could become familiar with the characteristics of the new agent.

Diagnostic Reagent Program

Although many laboratories are capable of preparing the antigens and antisera necessary for the diagnosis of influenza infections, a majority rely upon a central source for these materials. Since it was realized that early detection of influenza would depend upon the general availability of these reagents, in June 1957 approximately 100 laboratories were sent 15 ml. each of viral antigen prepared with the A/Jap/305/57, the A/Denver/1/57, and the B/GL/1739/54 strains. The last two strains are representative of recent variants of types

Laboratory Diagnosis of Asian Influenza

KEITH E. JENSEN, Ph.D., and RALPH B. HOGAN, M.D.

MODERN STUDIES of influenza are dependent upon information obtained in the laboratory. Clinical impressions and epidemiological observations may suggest influenza. But until virus isolation or antigenic experience has been demonstrated, an etiological diagnosis cannot be made since many other agents can produce an influenza-like syndrome (1).

The role of the laboratory in defining and following the spread of an infectious agent has never been more dramatically shown than in the present epidemic of Asian influenza. From the time of the earliest antigenic analyses (2, 3) it was predicted that this new variant of the influenza virus would spread rapidly and that epidemics would occur throughout the world. It is the purpose of this report to describe the laboratory facilities which are now engaged in a large-scale operation aimed at providing definitive information about influenza. Some of the results obtained during these activities will also be presented.

Laboratory Network

The Laboratory Branch of the Communicable Disease Center, Public Health Service, began to intensify its work with influenza in 1955, and at that time, the Virus and Rickettsia Section accepted responsibility for an influenza center of the World Health Organization. In 1956, the CDC Virus and Rickettsia Section established a Respiratory

Disease Unit at Montgomery, Ala., which was concerned with studies of influenza and several other viruses from the respiratory tract. This unit was designated by the World Health Organization to be the International Influenza Center for the Americas. In February 1957 this center sponsored travel for its director to the World Influenza Center in London for an exchange of concepts and discussions of problems.

The WHO influenza program consists of a worldwide network of collaborating laboratories and observers that report to the centers concerning the occurrence of influenza and forward virus isolates for antigenic analyses. This program was initiated in the United States in 1948 with approximately 40 laboratories participating.

Several State and Territorial health department laboratories have collaborated with the program during the past 9 years, and in the past few months, with help from CDC, many more of these laboratories have been able to participate in the program. There are now 45 health departments actively supporting the Public Health Service and WHO investigative projects. Currently a total of 135 laboratories are members of the American network. In the United States many of these are located at universities, institutes, and medically oriented organizations as shown below.

Earlier Observations

Variations among type A influenza viruses have been studied for many years but significant antigenic differences and relationships have been most clearly demonstrated by field trials of vaccine. In the laboratory, results of

antigenic comparisons of the different strains with cross-tests utilizing various antisera have provided detailed information about shared antigenic components. It has also been possible to show that periods of prevalence for virus strains with particular major antigens are reflected in patterns of antibody titers in human sera from various age groups. These developments have been reviewed elsewhere (4). It was evident from these past studies that a new set of type A variants of the influenza virus could be expected.

One of the lessons learned during the past 15 years was that influenza vaccines could be relied upon to be effective in reducing the incidence of the disease only when the vaccine formula included strains representative of the prevalent set of viruses. Recognizing this, the World Health Organization established strain study centers with many strategically located surveillance laboratories with the view toward rapid identification of virus isolates from each new outbreak. The viruses thus obtained in Singapore, Formosa, and Japan during May 1957 were strikingly different from previous type A strains. The incidence of antibody against these viruses in human sera was extremely low. The expected new set of viruses had appeared and promised to spread uninhibited throughout the world population. Anticipating this, the WHO program participants and responsible military and Public Health Service officials were alerted, and within a week prototype strains were sent to vaccine manufacturers for pilot studies and to the collaborating laboratories so that each could become familiar with the characteristics of the new agent.

Diagnostic Reagent Program

Although many laboratories are capable of preparing the antigens and antisera necessary for the diagnosis of influenza infections, a majority rely upon a central source for these materials. Since it was realized that early detection of influenza would depend upon the general availability of these reagents, in June 1957 approximately 100 laboratories were sent 15 ml. each of viral antigen prepared with the A/Jap/305/57, the A/Denver/1/57, and the B/GL/1739/54 strains. The last two strains are representative of recent variants of types

A and B. Antiserums prepared in chickens with each of these viruses were also distributed to laboratories in 5.0-ml. volumes. By the end of October, more than 30,000 ml. of antigen and 10,000 ml. of antiserum had been mailed to more than 300 laboratories.

Results of tests in July made it clear that the antigen prepared with the Japan 305 strain transferred serially in embryonated eggs was useful only in complement fixation (CF) tests and not in the hemagglutination inhibition (HI) method. Serum from patients convalescent from Asian influenza did not readily inhibit the hemagglutination of chicken erythrocytes by this virus. Meanwhile the virus had been instilled into the respiratory tract of ferrets, causing death, and infective suspensions of the lung were transferred serially in mice and later in eggs. This "animal-line" virus was much more sensitive to antibody in HI tests. Although mechanisms concerned in converting influenza strains from an antibody-insensitive phase to the more reactive phase are not understood, the phenomenon is well known and has been witnessed in many laboratories.

Another technical matter had to be dealt with, however, before the animal-transferred line of virus could be utilized. In addition to becoming more reactive with antibody, this line was also inhibited to a high degree by nonantibody substances in human and animal serums. The nonspecific inhibitors could not be digested with trypsin, but overnight treatment with solutions of periodate completely destroyed the troublesome inhibitors without markedly reducing specific antibody titers.

Therefore, beginning in August the antigen supplied to laboratories for the detection of Asian influenza antibody response has been that prepared with the egg-ferret-mouse-egg line (EFME). Directions for use of the antigen have been supplied. The viable seed for this Japan 305 variant and the other strains have also been distributed, and other materials, including human serums and normal allantoic fluids for control purposes, have been furnished upon request.

Information and Training Activities

Training in laboratory techniques in use at the International Influenza Center was pro-

vided in a 2-day workshop at the end of September. A class of 62 State and Federal technicians and directors was instructed in procedures to be followed in the isolation of influenza viruses from suspected materials. Standard methods for performance of the CF and HI tests were discussed and incorporated in laboratory exercises. Techniques for production of diagnostic reagents were outlined and considerable time was spent in discussing the interpretations of data.

The International Influenza Center met the problem of communicating pertinent recent information, or methodology, to laboratories by periodic newsletters and by collaboration with the CDC Influenza Surveillance Unit in the publication of a weekly influenza report.

Characteristics of Virus Isolates

The nature of this report does not allow a detailed description of observations made about the viruses isolated in the past few months. However, the following statements may serve to summarize the findings:

- All type A isolates obtained from various parts of the world since June are closely related antigenically to those sent from Singapore. The Asian set apparently has replaced the A' or FM family. Approximately 200 type A viruses have been forwarded to the International Influenza Center during this time, and all have been readily typed as the Asian variety. Three type B strains have been received, and these are very similar to the B/GL/54 strain contained in polyvalent influenza vaccines.

- The rate of successful virus isolations has been extremely variable (from 0 to 100 percent) and is obviously dependent upon several pre-laboratory factors, such as care taken in selection of patients, procedures followed in specimen collection, and transfer of specimens to the laboratories. In the laboratory, proper storage and treatment of specimens are necessary. Although the amniotic inoculation of 11-day embryonated eggs continues as the method of choice, many investigators have found monkey kidney culture useful (5). It is clear that amniotic fluids harvested from eggs should be tested with suspensions of guinea pig erythrocytes to detect the presence of hemagglutinating

virus. Often fluids shown to be negative with chicken erythrocytes were definitely positive with cells from guinea pigs. The value of sub-inoculating negative pools of amniotic fluids into another group of eggs has also been demonstrated. In several laboratories over 50 percent of the successful isolations were noted in this manner.

• Many of the positive fluids contained only low concentrations of hemagglutinating virus so that from 2 to 4 additional transfers were necessary before good titers could be obtained. Several strains have been obtained, however, which routinely reach titers of 1:800 or greater with 0.5 percent suspensions of chicken erythrocytes. Parallel tests of human serums with the Japan 305 strain and some of the more recent isolates have been carried out. One of these strains which yields higher titers may be substituted in the near future for the Japan 305 as the diagnostic antigen.

Serologic Diagnosis

Not all strains of influenza virus are equally sensitive to antibody in the HI or neutralization of infectivity tests. With the use of some variants the antibody response to infection in humans or animals cannot be demonstrated except by CF tests. On the other hand, many isolates have been studied which are as efficient as the Japan 305 EFME line supplied by the International Influenza Center. Mogabgab has found that fluids from infected monkey kidney cultures may also prove equally satisfactory sources of antigen (personal communication).

Many laboratories have reported diagnostic increases in antibody titers measured with A/Denver/1/57 or older type A influenza viruses in CF or HI tests although the isolates cultured from these patients were in the Asian set. These results are not surprising. The lack of specificity in antibody response to influenza infection, especially with CF tests, has been known for years. Repeated observations of antibody increases measurable in HI tests with strains of influenza virus no longer prevalent have led to the development of the "doctrine of original antigenic sin" (6). Although the mechanisms concerned remain poorly defined, it is clear from results of vaccination experi-

Comparison of number of antibody responses measurable by complement fixation or hemagglutination inhibition tests

Antibody response	Number	Percent
Total cases diagnosed ¹ -----	123	100.0
CF positive-----	94	76.4
HI positive-----	76	61.8
CF positive, HI negative-----	47	38.2
CF negative, HI positive-----	29	23.6
CF positive, HI positive-----	47	38.2

¹ Fourfold or greater increase in antibody titer measured with either test.

ments and serum absorption tests that antibody response to related antigens is often conditioned by previous antigenic experience. In this epidemic of influenza some patients have responded by producing increased antibody titers against the older virus strains with no detectable production of antibody against the Asian set. Viruses obtained from these cases were always of the Asian variety. Therefore, serologic diagnosis cannot be relied upon as a means of defining the set of the infecting agent but only as defining the broader immunological type.

The observations discussed above appear to lead to the logical conclusion that not much is to be gained by employing the HI test. The CF test will define the type of infection. The series of results compiled in the table, however, make it clear that both tests must be employed to effect a maximum of serologic diagnoses. Although the CF procedure was more often the more sensitive, many cases could not be diagnosed without the use of the HI method. Often high titers were found in the acute phase serum with the CF antigens while HI antibody was very low. In these cases the HI test is most useful. In a surprisingly low percentage of cases, only 38.2 percent, could the diagnostic rise be demonstrated by both tests.

Discussion

Legions of contributors to the store of knowledge about influenza have joined in an effort to study the characteristics of pandemic influenza. Although it is obviously too early at this time to define what has been learned, many laboratory

observations made during the past several years have been dramatically reconfirmed. The central role of the laboratory in providing etiological diagnosis of sporadic outbreaks and epidemics of influenza has been emphasized. Spread from country to country and within geographic areas has been carefully observed. There have been discussions in the past as to whether new variants appear simultaneously in several areas or the spread is from a single source. In the case of Asian influenza, at least, there can be no argument; the new variant arose in China and spread from that point.

Great interest has been focused on the question of whether strains of both the FM and Asian sets of A influenza would circulate. From June through November 1957 viruses isolated in great networks of laboratories all over the world have been of the Asian variety only. The greatest probability is that the older A sets will not be seen again in the near future. If the antigenic variations continue the course set during the past 24 years, we can expect modified forms of the Singapore viruses to appear and circulate during the next 10 years. The great shifts in antigenic composition of influenza viruses have occurred at least three times in our history at intervals of about a decade. Meanwhile, we can expect protection from influenza by vaccination or other antigenic experience with any of the Asian set of influenza virus strains.

Antibody response is often not strain specific in man because of previous conditioning by experiences with other variants of the immunological type. When epidemiological information is desired about more precise antigenic definition of the etiological agent, virus isolates must be examined. Although the serologic diagnosis of influenza is more frequently afforded by CF technique, a significant number of cases will be missed unless the paired serums are also tested by HI tests.

Berlin Epidemic, 1889

"Professor Virchow has recovered from his attack of influenza; several members of the Imperial family have also been attacked . . . The *National Zeitung* is censuring those who spread pessimistic theories about the epidemic. . . . Official data of the number of cases of influenza here have not been made. It is known . . . that but few families have escaped the plague, and that a third of the population has been ill with it. The medical press refutes the theory that there is any connection between the influenza plague and cholera, although it is known to be a fact that cholera has repeatedly appeared after an influenza epidemic."

—Cable report from *Der Deutscher Correspondent*, Baltimore, Md., *Public Health Reports*, December 14, 1889.

Influenza Control in the Armed Forces

HERSCHEL E. GRIFFIN, M.D.

THE HISTORY of the Armed Forces' interest in influenza is long and generally well known. Certainly the World War I experience has been recalled often enough recently to indicate the concern at least that far back. During that period 1 in every 5 men in the Army contracted influenza, and roughly 25,000 died from its complications. This is nearly half the number of battle deaths in the American Expeditionary Forces. The disease is still potentially important to the military as well as to the population at large.

The modern history of the Armed Forces' activities directed toward the control of influenza dates from December 27, 1940. On that date Lt. Col. James Stevens Simmons, the late dean of the Harvard School of Public Health, wrote a letter recommending the establishment of a "Board for the Investigation and Control of Influenza and Other Epidemic Diseases in the Army." Within 15 days approval was granted by the War Department, and the board, with its formidable title, was established. This agency, now the Armed Forces Epidemiological Board, and its Commission on Influenza are still active. The continuity of the agency is apparent from the fact that two members of the early commission are now on the board, one as its president, and two others are now directors of other commissions.

The major influenza control activities of the

Lieutenant Colonel Griffin, MC, U. S. Army, is chief of the Communicable Disease Branch, Preventive Medicine Division, Office of the Surgeon General, Department of the Army. This paper is based on comments at a symposium on Asian influenza held by the American College of Preventive Medicine and the health officers' section at the 1957 meeting of the American Public Health Association.

three military departments could be classified in several different ways. I have chosen to consider them under four main headings: surveillance, investigations, vaccination, and medical care. I shall briefly describe the activities of each of these areas and report our experience so far.

Military Surveillance

Surveillance is maintained, as in civilian public health, by periodic reporting augmented by special epidemiological reports when the occasion warrants. For example, the Army has 176 stations around the world which submit weekly telegraphic reports enumerating new cases diagnosed. Common respiratory disease, influenza, and pneumonia are among the reportable categories. By this means trends may be determined and the overall picture seen. More detailed information is submitted by special telegraphic reports in outbreaks of respiratory disease.

Laboratory surveillance is based on the central laboratory at the Walter Reed Army Institute of Research and extends through the area laboratories in this country and overseas. Each has facilities for viral isolation and serologic identification.

Military medical facilities also participate in civilian reporting programs. Station medical officers comply with the State and local reporting requirements. In turn the three Surgeons General report their experience to the Public Health Service for publication in the *Morbidity and Mortality Weekly Report*. Coordination of effort among military, State, Public Health Service, and World Health Organization laboratories has been close from the beginning of man's ability to type the virus.

Through this surveillance an increasingly clear picture of Asian influenza among the military has emerged.

The most important characteristic of influenza to the military in 1957 was its high attack rate. This was the predominant feature of the early epidemics in Asian populations. But when the epidemic reached our military and naval units in the Far East, where we could focus closer investigative study, it became apparent that the attack rate was not constant. In some units the rate reached 65 percent, in others 10 to 20 percent, and occasionally there were only a few cases. This variation, it was soon determined, was not due to preexisting immunity since antibodies to this virus were entirely lacking in this group. It appeared to be a function of crowding and closeness of contact.

The high rates occurred in units where the men lived, slept, ate, and worked together, such as those aboard naval vessels and in recruit training camps. When the populations were not so concentrated, the rates were low. For example, the outbreak at the San Diego Naval Training Center began so explosively that many first thought it would turn out to be adenovirus disease. Moreover, the rates in recruits were high, and in the cadre, who lived in their own homes, the rates were low. But it *was* influenza. This pattern has now been repeated many times.

A companion feature has been rapidity of spread, or perhaps more precisely the almost simultaneous occurrence of geographically widely separated outbreaks. How the disease first swept through Asia is well known. Its successive occurrence in countries around the world and the early widespread seeding in the United States have been described.

The first confirmed military outbreak in this country occurred in an east coast naval station early in June 1957. For 3 months the laboratories across the country reported occasional virus isolations and significant titer rises from sporadic cases. But there were few outbreaks. Although the virus was widespread, the respiratory disease rate for Army troops in the United States remained relatively constant, below 100 per 1,000 per year in the weekly reports.

Then, in the first week of September, many special epidemiological reports were received. The rate for Army personnel in the United States rose in 5 weeks to more than 750 cases per 1,000 per year, as some 30,000 cases occurred. By mid-October, though, the rate was headed precipitously downward again. At the end of the first week in December it was down to 215. Thus, although person-to-person spread may account for infection with the virus, it alone cannot explain the pattern of the occurrence of epidemic influenza in the Army. The pattern in naval fleet units is a little clearer because of the closeness of the contact and more nearly resembles the spread in Asia or the occurrence of disease in families.

If one focuses attention upon individual bases and ships rather than upon the armed services as a whole, an important mitigating feature of the disease is brought to light. This is the short duration of outbreaks. In military experience most have run their course in 4 to 6 weeks, except where there have been additions to the population. This brevity of duration significantly lessens the effect of even intense outbreaks. In those outbreaks where the overall attack rate reached 25 percent, only 5 to 6 percent were ill at the peak, and then for only a few days. Prevalence is a better index of impact of disease than is incidence.

The laboratory has contributed significantly to surveillance. Its first function is categorization of the outbreak through confirmation of the diagnosis. Our practice is not to submit every case of respiratory disease to the laboratory for study, but to investigate throat washings and serum pairs from a small sample of characteristic cases early in the outbreak. Once the outbreak is categorized as influenza, cases are diagnosed clinically.

Early in the summer it became apparent that "all is not flu that fevers." Outbreaks presumptively diagnosed as influenza were proved in the laboratory to be as diverse as streptococcal exudative pharyngitis, common cold, and salmonellosis. One wonders at the reliability of the cumulative numbers being generally quoted.

The laboratories have been examining the homogeneity of the virus. Remember that early in 1957 an influenza A' virus was widely

disseminated. In April the Asian variant started its world tour. The question has been raised as to whether another strikingly different A virus would appear this year. Experience would say no, and so far the laboratory has borne out experience. But vigilance is being maintained for the early detection of the unexpected, should it occur.

Surveillance, then, has identified the close, continuous contact, such as that of the family or the crew of a ship, as the hazardous contact. Potential control measures involve preventing transmission of the virus within these close groups, rather than curtailing public gatherings. However, this does not preclude closing schools for administrative reasons because of high absentee rates or illness among teachers.

Investigative Efforts

Investigations are being carried out on many fronts so that when the time comes to draw conclusions about this epidemic, those conclusions may be based on data and not on speculation. We believe that we would be seriously remiss to allow this, the most significant occurrence of influenza in almost 40 years, to pass poorly or inadequately documented.

These investigations are being conducted at all levels. Prototype protocols for the epidemiological description of outbreaks at individual installations have been widely distributed. When they are returned, there will be a large body of information reported in comparable format, with data commonly categorized. We hope that this procedure will allow pooling of the data and permit an orderly and logical progression from the specific to the general when evaluations are made.

Military laboratories and research groups are also conducting studies. The early work of Dr. Maurice R. Hilleman and the Walter Reed Army Institute of Research group in identifying and categorizing the virus and in evaluating its antigenicity may be mentioned. Important work in clinical, laboratory, nursing, and other aspects of the situation is being done by other laboratories. We are continuing to finance the projects of the Armed Forces Epidemiological Board and its Commission on Influenza.

All this research, which represents a rather considerable commitment of personnel, facilities, and money, is not considered an ancillary function or an esoteric exercise, but an essential control activity. Just as the knowledge gained from the more than 15 years of previous study allowed prompt action when the new strains appeared, so the research carried out this year will continue to improve our position of preparedness for the future. At any rate, an effort is being made to avoid what Dr. Edward G. McGavran has categorized as the "loss of invaluable information through the failure to observe and record experience."

Vaccination by the Services

Vaccination represents the only really effective control measure available in combating influenza. The actual program of immunization is simple. Military personnel worldwide have received two doses of vaccine. Overseas, the same course was offered on a voluntary basis to civilian employees and dependent personnel. At installations in this country where supplies exceeded military need, one dose has been offered to dependents and civilian employees.

I have been asked to comment on the intracutaneous route of administering influenza vaccine.

The primary reason this route has been considered at all is that it enables the available supply of vaccine to reach a larger segment of the population. Hilleman and others have reported that the antibody response to intracutaneous vaccination was "almost as good" as the greater amount given subcutaneously. He noted that "this finding may be significant in situations where shortage of vaccine necessitates stretching the supply." Similarly, the special Committee on Influenza of the American Medical Association stated that the subcutaneous route was preferable, though the intracutaneous route was offered as a possible alternative.

In the Armed Forces all past studies and experience regarding the preventive effect of the vaccine, as opposed to antibody stimulation, have been based on the subcutaneous route. So this route was decided upon if the supply should prove sufficient. In one service, the supply for

the first dose was limited and the intracutaneous route was used in part of its personnel. The subcutaneous route was used throughout for the second dose.

As yet we have no data on the protective effect of the intracutaneous injections. Studies are under way to provide factual data on which to base future action.

Experiences in Medical Care

It is not customary to consider medical care a control activity. But in this disease care and control are interrelated. Clinical features have epidemiological significance, and epidemiology guides care. There has been nothing peculiar to the military in its hospitalization and therapy policies. Conservatism has been the rule. Segregation of patients, preferably without hospitalization for the uncomplicated cases, and symptomatic therapy with avoidance of antibiotics have been practiced in military as well as in civilian medicine.

The first action taken in medical care was obviously operational planning. It was necessary to estimate the capability of the military medical services in order to provide personnel, supplies, and facilities to meet the load. Because these medical services are designed for rapid expansion of their reserve capacity, and personnel and supplies are mobile, it was concluded that the capability was sufficient to meet the anticipated load.

The first test of this conclusion was in the Philippines. Clark Air Force Base reported

a sharp, severe outbreak, but needed no outside help to manage it. Now that there have been scores of such experiences, it has become clear that the military medical services are indeed capable of handling outbreaks of this magnitude. Even aboard ship, where expansion capability is limited, facilities have been adequate, though at times severely strained.

Clinical experience may be briefly summarized. Cases have been acute, with temperatures averaging about 103° F. but recovery has been rapid. The average time lost has been about 4 days. Pneumonia diagnosed on clinical grounds has been seen in less than 1 percent of respiratory disease admissions. This includes primary pneumonia, with no association with influenza. In about 5 percent of the respiratory cases where chest X-rays have been taken routinely, some degree of pneumonitis has been reported.

Association of the influenza virus and a bacterial hitchhiker has not been observed, even in areas where streptococcal disease is endemic. In the Army one death has been associated with influenza. The few other pneumonia deaths have been intensively studied, but no evidence has been elicited which would indicate that influenza played a role in them.

In regard to the future, I can say only that this is our program; so far it has served us well. We intend to continue it as described, though ever alert to a change in the situation which would warrant modification or revision. We are prepared for such a change, while not necessarily predicting it.

Public Information and Education

J. STEWART HUNTER

ON SEPTEMBER 1, 1957, a New York newspaper carried a roundup story on Asian influenza with this lead sentence: "The greatest teamwork in medical history has been stimulated by the threat of a spread of Asian influenza this fall." Later in the story the reporter wrote: "Communications from Geneva [World Health Organization] through the world's capitals to laboratories, health departments, universities, vaccine manufacturers, local physicians, and the general public is the key to today's medical teamwork."

Undoubtedly the Nation's readiness with respect to Asian influenza owed its heaviest debt to intercommunication among nations, among medical and scientific and public health professions, between industry and government, and between all of these elements and the populace. The interchange of information has been constant since June 10, 1957, when Surgeon General Leroy E. Burney called the first meeting of representatives of medical and health professions to discuss the influenza epidemics then appearing throughout the Far East and to consider courses of action should the disease spread to this country.

In this effort the role of public information and health education as an organized and integrated part of the Public Health Service's Asian influenza program has been fully recognized and fully employed.

In testimony before the Senate Appropriations Committee on behalf of a request for sup-

plemental funds for influenza activities, the Surgeon General said:

In the last analysis, the success of any large-scale effort to control an influenza epidemic depends upon an alert and informed public. We must avert the dangers of indifference on the one hand, and of undue hysteria on the other. This calls for current and reliable public information on the exact nature of the problem and on the actions which need to be taken. We plan to provide these informational and educational services, in cooperation with State and local health departments and professional groups.

The Congress appropriated \$110,000 for public information and educational purposes.

The Public Health Service has long recognized the importance of these activities, and information and public education are implicit in all its programs. In fact, the Service's basic legislation directs the Surgeon General to report on health matters periodically to the public and to the Congress, and to engage in health education activities. The Asian influenza program, however, represents a positive and explicit directive from the Congress to carry on an information campaign.

Two Related Tasks

In this campaign, there were two distinct but related kinds of tasks. The first was to inform the public about Asian influenza and to alert people to the possibility of an epidemic in this country and of the actions taken to deal with it. The second was to encourage use of the new influenza vaccine as the only preventive measure available.

The first task was essentially a public information program. Like all similar programs, it entailed not only reporting fully on developments as they occurred but an educational effort

Mr. Hunter is Assistant to the Surgeon General for Information, Public Health Service. This article is based on a paper presented at the 1957 meeting of the American Public Health Association in Cleveland, Ohio.

as well. The major emphasis was through mass media: newspapers, magazines, radio, television, films, pamphlets, and exhibits.

These facilities offer the most effective way of delivering a message to the eyes and ears of millions in the shortest possible time. This, of course, was the necessity which we faced. Information fully reported and properly interpreted through such media obviously is fundamental to the development of public understanding. There are, of course, many useful and essential channels.

The second task, to encourage use of vaccine, called for a sustained campaign of health education. In this campaign, the Service used both the mass media and the techniques of personal communication, although the emphasis, because of the limitations of time, had to be on the former. One of our important goals was to provide assistance to State and local health agencies, to professional groups, and to industry in their own information and health education programs.

To accomplish the first task, that of alerting and informing the public, the Service strengthened and intensified its means of imparting information through normal channels. For example, press releases were issued and press conferences were held immediately following all major policy decisions. Between June 7 and the beginning of December, the Service issued 35 press releases on Asian influenza alone, averaging more than 1 a week. In addition, the major meetings, such as the Surgeon General's special conference with the State and Territorial health officers in August, were open to the press and to representatives of other media. And, of course, State and local health officials, medical societies, and others interested in the program were kept regularly informed of incidence, vaccine supply, and other developments.

Considerable time and attention were given to working with magazine editors, staff writers, and free-lance contributors. Articles on Asian influenza have appeared in at least 32 magazines of wide national circulation, including *Reader's Digest*, *Life*, *Good Housekeeping*, and the various news weeklies. An incomplete tally shows that 60 such articles appeared from September through November 1957. In addition, there were numerous reports in specialized jour-

nals, trade magazines, house organs, and regional and State publications.

Papers and articles also appeared regularly in professional and scientific journals. Within the same 3-month period, for example, 14 articles on Asian influenza appeared in the *Journal of the American Medical Association*, several of them written by Public Health Service officials. There were similar articles in the periodicals of public health, nursing, pharmaceutical, and other professional organizations.

This was in line with another implicit directive from those who planned and administered the influenza program: a free and rapid interchange of information among professional groups. It was the job of public information and education personnel to apply their specialized skills and techniques to keep the information flowing and current. The material from the special meeting with the State and Territorial health officers, for example, was quickly reproduced and widely disseminated. The journals of the American Public Health Association, the American Medical Association, the American Hospital Association, the American Pharmaceutical Association, the nursing organizations, voluntary health agencies, and the State health departments spread the word rapidly to private physicians and other key people.

In fact, effective information services originated from a wide variety of sources and were conducted in an excellent spirit of cooperation. It should be emphasized strongly that the Asian influenza information program has been a cooperative enterprise throughout, with the noteworthy assistance of the communications industry itself. The reporting of the Asian influenza story by press, television, and radio, and by professional and specialized organs has been restrained, responsible, and enlightened. The newspapers and other media have almost without exception shown a ready understanding of the problems faced by health officials and a willingness to help.

A good example of this kind of cooperative action was a television program late in August on Westinghouse station KDKA in Pittsburgh. This program was produced by a joint effort of the television station, and the American Medical Association, the University of Pitts-

burgh, the Allegheny County Medical Society, and the Public Health Service. The participants included Dr. Burney and other officers of the Service, and Dr. George F. Lull of the American Medical Association. The show was carried in five major cities and over the educational television network of the University of Michigan. It was also kinescoped, and prints were sent to all the States. By mid-November, the film had been shown more than 200 times on 150 television stations in 41 States.

Many other television and radio appearances by senior officials of the Service, of State and local health departments, and of professional organizations also helped tell the story to the American people.

Films and Pamphlets Issued

In another information field, the Public Health Service developed extra footage and otherwise brought up to date a film made in 1950 entitled "The Epidemiology of Influenza." Copies of this film were distributed for use by the States. Reports received by the Service indicated that the film had wide use on television and at public and professional meetings.

A number of new publications on influenza were developed by the Public Health Service and given wide distribution. These included a fact sheet on Asian influenza, a revision of the basic health information leaflet on influenza, and pamphlets entitled, "What You Should Know About Asian Flu" and "If Asian Flu Comes to Your Community."

Pamphlets and other educational material were also issued by others involved in this effort. The American Medical Association developed a packet of material for State and local medical societies. The American National Red Cross issued a special Asian influenza information kit to its State and local affiliates. Voluntary health agencies, professional groups, the pharmaceutical organizations, and industry distributed special bulletins, pamphlets and articles for the general public as well as for physicians, pharmacists, and other health personnel.

Speaking engagements, including formal papers and informal talks before a variety of professional and public groups, helped inform additional thousands of people. Public Health

Service officials delivered at least 23 addresses on Asian influenza from September through November, an average of about 2 each week. These were given in such major cities as New York, Boston, Philadelphia, San Francisco, St. Louis, and Chicago, and before groups ranging from local civic clubs to meetings of national voluntary and professional associations.

All of the foregoing, as well as other communications techniques, were used to perform the first of the two tasks previously mentioned, to inform the public. These techniques also served as an integral part of a sustained health education campaign. In addition, other educational measures were developed to encourage vaccination against the infection. All State health educators, for example, received guides on how to organize for local community action specifically adapted for this campaign. Health educators were assigned to the regional medical officers of the Public Health Service to work with States and communities and to conduct special surveys of local problems, needs, and attitudes.

A series of 14 radio spot announcements, 4 television announcements, and 5 newspaper advertisements in varying sizes were sent to public health educators and information personnel in all of the States and Territories for their use in local situations. In the 3-month period, 15 such mailings were completed. The materials were designed to be flexible and easily adaptable to the needs of local communities.

A great stimulus to the vaccination promotion program was a special campaign launched as a public service by the Advertising Council, Inc., in early November. Sponsored by the Public Health Service and the American Medical Association, the campaign was prepared by the voluntary task force advertising agency, Young and Rubicam, Inc. Its purpose was to carry the message of vaccination to all the newspapers and radio and television stations of the country. A kit containing four newspaper advertisements in varying sizes was shipped to all newspapers in the United States. Similar material was sent to all television and radio stations. The television spot announcements were narrated by the noted commentators, Edward R. Murrow, John Daly, and Dave Garroway.

Copies of related Advertising Council materials were sent simultaneously to State health officers and their health education staffs. Local sponsors of the messages were asked to check with their medical and public health authorities before using the advertisements in newspapers or on the air. In this way, State and local agencies were given an opportunity to participate in the campaign. Several local information and education efforts, in fact, were geared to the appearance of these ads.

In this effort, the Public Health Service had the benefit of early assistance and counsel from an ad hoc Advisory Committee on Information and Education, whose members were health educators in State and voluntary health agencies. The committee included Robert Yoho of Indiana, James Quinlivan of New York, Elizabeth Reed of Florida, Thomas Gibson of Georgia, Milton Kossack of Louisiana, and Sol Lifson of the National Tuberculosis Association. They responded generously to the request of the Public Health Service for advice on these matters and contributed substantially to the success of the program.

The Program's Effect

It is pertinent at this point to ask, and attempt to answer, the questions: Was the program successful? Did it achieve its purpose "to alert but not to alarm" the Nation and to encourage people to be vaccinated? The evidence seems conclusive that the campaign did indeed achieve its objectives. Probably never before in the history of the Nation has the public become so quickly and so well informed on a matter of public health importance.

The findings of the Gallup Poll of September 23, 1957, are worth repeating in this connection. Of the adults questioned:

- 92 percent had heard or read of Asian influenza.
- 76 percent knew that there was a vaccine against the disease.
- 65 percent planned to be vaccinated.

These findings are all the more remarkable when one considers the unprecedented speed of the entire influenza development. Within less than 5 months a new strain of influenza virus was identified and isolated; a new vaccine was developed, tested for safety and effec-

tiveness, and produced in mass quantities; plans were developed and put into effect for a nationwide voluntary distribution system; millions of Americans were vaccinated; and an emergency medical care program was devised and put into effect in many local communities.

Communications paved the way for quick and effective action at every point in this development. Without a strong and active information program, the public might have floundered in ignorance and fear and there might have been uncertainty among professional groups. With it, there was a rational period of preparation and a cooperative mobilization of resources. This is not unique or even surprising. The American people, when well informed with the facts, react in this fashion.

The evidence of acceptance and understanding is clear. But was the job well done? Was too much information centralized in Washington, to the detriment of local programs? And was the entire development sensationalized beyond its public health significance either by the Service or others engaged in public information?

We believe that the answer to these questions is "No." While everything was done to alert people to the situation and to see that the information disseminated was accurate, it must be kept in mind that Asian influenza was not made into front-page news by virtue of a public information program. The story had many elements of newsworthiness: a disease of mysterious, sudden origin in a remote region, a rapid spread throughout the world, a catastrophic potentiality, and a unique scientific and industrial achievement of swift identification of a new virus strain and large-scale production of a new vaccine.

The problem was not whether to publicize the Asian influenza story. The story would have been told inevitably by the communications media because of its inherent public interest. The problem was instead to use the techniques of communication and education to let reporters, the public, and the health professions know precisely what was at stake, why action was necessary, and what kind of action

was called for by each group. And the aim was to draw each group into the national effort, as an active planner and participant.

Joint planning and joint action in the information and education effort as well as in other phases of the program were key elements in the control of Asian influenza. One of the important byproducts of this campaign has been the strengthening of relationships among

those responsible for communications programs in Federal, State, local, and voluntary health agencies. This should stand us in good stead not only in the event of future emergencies but in the conduct of information and education for continuing health services. Information is vital to health programs, and its vigorous employment will help bring closer the goal of better health for all.

PHS Material on Influenza

The following materials prepared or issued by the Public Health Service relating to the epidemic of Asian influenza include films, publications, and articles in *Public Health Reports*.

Film

The Epidemiology of Influenza, an updated 1950 film (16-mm., sound, black and white, 13 min.), shows the fight against influenza since the pandemic of 1918. The historical significance, behavior, and periodicity of the disease, its clinical picture, the WHO program including the establishment of look-out posts, the physician's role in reporting, and laboratory procedures are all depicted. It can be obtained on loan from the Communicable Disease Center, Public Health Service, Atlanta, Ga.

Publications

Proceedings of the Special Conference of the Surgeon General of the Public Health Service with the State and Territorial Health Officers, August 27-28, 1957, mimeographed, available in limited quantities, without charge, from Public Inquiries, Public Health Service, Washington 25, D. C.

Public Health Monograph No. 48 (PHS Pub. No. 544), A Review and Study of Illness and Medical Care, with special references to longtime trends, by Selwyn D. Collins, 1957, 86 pp. (An extract from

this study, Influenza in the United States, 1887-1956, covering pages 51-74, is published as a separate.)

Articles

The September, October, and November 1957 issues of *Public Health Reports* as well as this one carry papers on influenza:

In the September Issue—

Influenza Epidemic Alert, by Surgeon General Leroy E. Burney, p. 767.

Influenza Epidemics During 1951-56 With a Review of Trends, by Selwyn D. Collins and Josephine L. Lehmann, pp. 771-780.

A short report on the Asian Strain of Influenza A with a Calendar of Major Events in the 1957 Outbreaks, pp. 768-770.

In the October Issue—

The Philippine Influenza Epidemic of 1957, by Matthew Tayback and Arturo C. Reyes, pp. 855-860.

Testing Influenza Vaccines at NIH; Selected Steps in the Procedure To Insure Safety, Purity, and Potency (pictorial), pp. 861-864.

Pan American Cooperation on Influenza, p. 917.

In the November Issue—

Health Officers' Meeting on Asian Influenza, pp. 998-1000.

Mobilization of Private Physicians

HAROLD C. LUETH, M.D.

THE THREAT of an Asian epidemic in the United States confronted the medical profession early in June 1957. The board of trustees of the American Medical Association promptly designated the Committee on Civil Defense as the Special Committee on Influenza and assigned it the additional task of exploring the possibility of Asian influenza in the United States, the extent and nature of the threat, and the means with which the threat could be met.

On July 9, representatives of the American Medical Association, the American Hospital Association, and the Public Health Service met at the AMA headquarters to draw up a program whereby the individual physician could be informed of his role should the threat be realized.

As a result two principal programs were developed. One provided the physician with necessary information; the other dealt with organizational matters.

To assure the physician that he would get all the scientific information concerning the biology, epidemiology, clinical characteristics, and therapy of Asian influenza, the information program prepared articles and notices for publication in the *Journal of the American Medical Association* and special notices for State and county medical journals.

Dr. Lueth is clinical professor of medicine, University of Illinois College of Medicine, Chicago. He is a member of the American Medical Association's Council of National Defense, chairman of the Committee on Civil Defense, and chairman of the Special Committee on Influenza. This paper is based on comments at a symposium on Asian influenza held by the American College of Preventive Medicine and the health officers' section at the 1957 meeting of the American Public Health Association.

The organizational program was divided into several different activities. First, State and county organizations were notified and advised to take immediate action on the possible threat. One of the first things noted, of course, was that vaccination was the only possible means of combating Asian influenza. It was simultaneously recognized that the vaccine would be in short supply, requiring some scheme of allocation.

Next, the Special Committee on Influenza suggested that the vaccine be allocated on the basis of local determination, using the facilities and resources within communities. It was assumed that the local health profession working with the local public health officer and other community officials could best ascertain how vaccine in short supply could be divided and utilized advantageously.

An action group was then formed to allocate the determinable amount of hospitalization available. It was seen immediately that there would be a wide demand for hospitalization through Blue Cross, Blue Shield, and other insurance programs. Since it would be difficult for the physician to deny hospitalization to a large group of people, the committee felt that some scheme should be forthcoming for orderly use of hospitals.

Because of these problems, notification of the decisions were authorized by the board of trustees on July 20. At the same time, the board designated two of its members, Dr. Hugh Hussey and Dr. James Appel, to sit with the Special Committee on Influenza. By July 26, the notifications went out to each of the county and State representatives, and they were urged to take action.

It should also be pointed out that by July 20 there was some concern about a possible wide-

spread, injudicious use of antibiotics, and a preliminary statement was sought from the Council on Drugs of the American Medical Association. The council issued a statement advising a reasoned and cautious scientific application of antibiotics in proved and indicated cases.

On August 14, the Surgeon General of the Public Health Service called a meeting in Washington, D. C., for all representatives of national health agencies and voluntary health groups to decide how to cope with this particular problem. Three recommendations ensued:

First, the Surgeon General's program should be fully supported and endorsed by all organizations whose representatives were in attendance.

Second, local health groups or councils should determine how vaccine and hospitalization should be allocated within local communities.

Third, a meeting of the State health officers should be called by the Surgeon General at the earliest possible moment so that their efforts could be integrated or coordinated with other agencies.

The State and Territorial health officers meeting was held in Washington on August 27 and 28, and one of the essential ideas that came out of the meeting, in addition to those dealing with cooperation and allocation, concerned the proper use of laboratory work. There was some apprehension that physicians might not at first use the resources of laboratory techniques to pinpoint the occurrence of Asian influenza, but would rely on clinical signs. It was also feared that, in some instances, too much public awareness would lead overanxious patients and physicians to flood laboratory resources with an unnecessary number of specimens. A carefully worded statement urged physicians to use laboratory resources to determine the presence of an epidemic, but to allow the State and Public Health Service laboratory officers to select samples for testing.

The Council on Drugs, on September 7, enjoined physicians to use antibiotics only when indicated and then to use them in large enough doses to combat the offending secondary type of organism.

On September 19 the public information program was launched with a television announce-

ment by the president of the American Medical Association. Recordings and scripts for radio and television were on hand for local members of the profession to use should influenza strike their communities.

By September 27 the program had developed and events had changed enough to warrant a second notification from the Special Committee on Influenza to the same county and State medical societies and health groups, advising them of current developments and again asking them to take appropriate action.

It is interesting to note that those medical societies with well-organized plans and with active national emergency medical service committees or civil defense committees quickly took this material, redefined it, reworked it in the light of their particular needs, and disseminated it to their local groups. Just to show how rapidly some States worked, the Mississippi State Medical Association was able to prepare and mail within 1 day after notifications were received a plan for the entire State.

On September 27 the Special Committee on Influenza took definitive action on the use of false and misleading information concerning the efficacy of drugs. As soon as Asian influenza received wide publicity, many took the opportunity to claim some therapeutic advantage of their particular pharmaceutical product. The Special Committee on Influenza emphatically restated that false and misleading statements about drugs should not be published.

On October 5 the Special Committee on Influenza reviewed the whole program and reemphasized its importance. While the committee was pleased that the program went on rapidly and efficaciously, it was cognizant of deficiencies and failings, and in an effort to have a more effective future method of operation each State and county medical society was requested to submit its particular program to headquarters of the American Medical Association. These reports will be carefully and critically examined as soon as possible in order to formulate a standby national program that will be useful should it be required in any future emergency.

In summary, what has the individual physician learned as a result of this program?

First, the physician has been profoundly impressed with the tremendous network and capa-

bilities of all governmental health agencies working in such close cooperation so as to make it possible to identify, isolate, and recognize this particular virus, and to make the information obtained readily available to physicians.

Second, the physician has recognized the importance of having channels of communication open to physicians whereby they can be alerted and quickly supplied with medical information.

Third, he has found that those physicians who had good immunization programs as part of their daily practice could incorporate the Asian influenza program without any difficulty.

Fourth, the thoughtful physician has discovered that his place in the community has been

more thoroughly defined and delineated. He sees more clearly where he fits in relation to the local health officer, the professional agencies, and voluntary health agencies in carrying out his daily work as a physician.

Fifth, the physician has learned that the Asian influenza program is essentially an emergency medical service program and a phase of civil defense. A critical review of each physician's actions during the program should result in the adaptation of the best and most significant ideas for his daily practice, leaving those which are not a part of daily practice readily available in case they are ever needed again.

Mattison Appointed APHA Executive Secretary

Dr. Berwyn F. Mattison, secretary of health of Pennsylvania since 1955, has been named executive secretary of the American Public Health Association.

Previously, Dr. Mattison was commissioner of health in Erie County, N. Y., from 1948 to 1954, and in Yonkers, N. Y., from 1946 to 1947. He entered the New York State Department of Health in 1941, serving, during the next 6 years, as assistant district State health officer and district State health officer.

Dr. Mattison received his medical degree from McGill University, Montreal, Canada, in 1936, and his master of public health degree from Johns Hopkins University in 1941.

In addition to membership in numerous professional societies, Dr. Mattison holds a number of committee and board appointments including chairmanship of the Advisory Committee to the Surgeon General (PHS) on Training Needs in Public Health and of the Pennsylvania Advisory Health Board.

Lessons in Planning for Epidemics

MACK I. SHANHOLTZ, M.D.

GIVEN FOREWARNING of an epidemic of influenza, early planning is an obvious step. We have learned a great deal from the experience of planning for the present epidemic.

In working with the Asian influenza epidemic, we have learned some things that will be useful in planning for the total fight against influenza. In addition to what we know about the Asian influenza virus, the vaccine, and immunity through use of the vaccine, we have learned that cooperation between State and local health departments and State and local medical societies is necessary for the success of any program combating influenza.

I believe we have learned, too, what the health department's proper role is in such an activity. The health department acts as an information center, first of all, for the dissemination of educational material. It also acts as a central tabulation center on cases, distribution, and deaths. It helps in setting up priority systems for the vaccine as well as diagnostic facilities for the identification of the virus. And it helps organize community resources for stricken areas.

The experience gained from the present epidemic also suggests measures that should be undertaken—and others that should be avoided—in the event of another epidemic.

Dr. Shanholtz is the State health commissioner for Virginia. He is also secretary of the Association of State and Territorial Health Officers. This paper is based on comments at a symposium on Asian influenza held by the American College of Preventive Medicine and the health officers' section at the 1957 meeting of the American Public Health Association in Cleveland, Ohio.

Should that event come to pass, I should suggest the following:

Planning should be done by the two State groups most vitally interested and concerned in setting up a control program: the State health department and the State medical society. The first meeting for consideration of epidemic control should be limited to these two groups; larger groups of people, of whom some may not be too well informed, will serve only to waste time and create confusion. It is better that a small group devise the framework of a control program before calling in others to fill in the details. After the first meeting, however, allied medical groups, voluntary health agencies, and appropriate community groups should aid in preliminary planning.

In the event of another epidemic, State and local health departments and medical societies should present a united front to further a successful community control program. At the very outset, a State policy must be formulated covering all aspects of such a control program. Local groups can then plan programs for their respective communities within the framework of State policy. The State should also anticipate emergency needs and locate special resources.

I should recommend, as another important phase of planning, the development of an education program that would prepare every citizen for an epidemic. On this score, I might suggest that we begin at home.

As for educational materials, I feel it is necessary to have a special joint committee, with representatives of organized medicine on it, to appraise the various educational materials that might be sent out to the public. In the beginning of the Asian influenza epidemic we

were afraid of overselling and creating a panic. We were also afraid of creating a greater demand for vaccine than we could supply. A joint committee decided then, and should decide in the future, the quantity and timing of information.

Future epidemics could be handled more easily if local communities were organized, with certain variations to fit particular situations, very much like the States. Some community groups, of course, are already organized. Local health groups, such as health departments, medical societies, nurses' associations, and pharmaceutical associations, and voluntary health agencies, such as the Red Cross and civil defense groups, are examples. But there are other groups that could be organized more effectively; I mean those working in education, industry, and community affairs.

It might also be well to consider the reservoir of retired, inactive nurses that could be used more effectively. The Red Cross and civil defense agencies have listed them. I feel that we ought to have these nurses on a standby basis where they might assist in an emergency.

Other resources could be tapped. An epi-

demio calls into being a vital need for additional transportation and clerical personnel and emergency telephone services. It might also be worthwhile to consider providing nursery care for children of graduate nurses who are called to active duty.

My final recommendation concerns a better means of allocating vaccines, especially when the supply is far smaller than the demand. In the 1957 influenza epidemic, many people wanted vaccine and wanted to be first. Some managed to get vaccine in spite of priority grouping and advice. And some large groups received vaccine ahead of any classification. Some of the ensuing anxiety may be attributed to overeducation, but my own feeling is that much of the fear was engendered by a memory of the 1918 epidemic. In any case, a more coherent system of allocation is needed.

These are some of the lessons we have learned, as I see it, from the Asian influenza epidemic. Working together has been a very good exercise for all of us. We have learned again, above everything else, that a united, co-operative effort on the part of health officials and practicing physicians is all important for success in any endeavor in the field of public health services.

Emergency Recruitment, 1918

"Better than volumes of reasoned arguments, the present epidemic of 'Spanish' influenza has shown in concrete form how important it is to have attached to the United States Public Health Service a reserve organization which can be mobilized in times of emergency.

"With the widespread occurrence of influenza in the vicinity of Boston, and the unmistakable signs of its beginning elsewhere, urgent calls were addressed to the United States Public Health Service to furnish medical and nursing relief to stricken communities. All available regular officers were detailed to the stricken communities, but the number available for such detail was insignificant compared to the urgent need occasioned by the epidemic. Moreover, the bureau had no nurses available for service in epidemic."

—*Public Health Reports, October 25, 1918.*

Research Programs on Asian Influenza

JUSTIN M. ANDREWS, Sc.D.

NEARLY a month before the first group of cases of Asian strain influenza were diagnosed in American civilians (high school conference at Davis, Calif., June 21-30, 1957), special research on various aspects of this disease had been started at the National Institutes of Health of the Public Health Service. Since then, 6 of its 13 major subdivisions, the Division of Biologics Standards, the National Institute of Allergy and Infectious Diseases, the National Heart Institute, the National Institute of Mental Health, the Clinical Center, and the National Institute of Neurological Diseases and Blindness, have participated in meeting this investigational exigency.

In late August, a special conference of State and Territorial health officers was called by the Surgeon General to review developments and to coordinate and plan future activities relative to the epidemic. At this meeting, the recommendation was made that a group of outstanding medical scientists representing the several areas of specialized knowledge associated with influenza be appointed to advise the Surgeon General regarding research planned to minimize the morbidity and mortality resulting from Asian influenza. This suggestion was implemented in September.

The following is a brief recapitulation of influenza research being carried on or supported by the National Institutes of Health and of the organization and accomplishments of the Public Health Service Influenza Research Committee.

Division of Biologics Standards

While influenza vaccine is not a new product and new strains have been added to the vaccine in the past, the vaccine situation faced

by the Division of Biologics Standards and by the manufacturers in the early summer of 1957 differed from previous ones in the degree of urgency and in the size of the production goal.

Various isolates of the Asian influenza virus were supplied to licensed manufacturers of influenza vaccine by the Division of Biologics Standards as soon as they were received. The first of these, A/Jap/305/57, was sent out by the division on May 12, 1957. One of the immediate problems encountered with the new strain was the selection of a particular isolate which could be best adapted to producing satisfactory virus growth in the chick embryo. In addition to Japan 305, A/Jap/306/57, A/Jap/307/57, A/Formosa/1/57, and A/Singapore/1/57 were studied by both the division and the manufacturers for growth potential and other characteristics. As a result of these studies, it was decided that no particular isolate would be designated for vaccine production, but that the manufacturer would use, from among those distributed by the Division of Biologics Standards, the Asian strain isolate showing the best growth characteristics in the hands of the individual manufacturer. The type of potency test used with previous influenza vaccines had been of the mouse protection type which requires 4 weeks or longer to complete.

Initially, it was not possible to use this test for the Asian strain vaccine since a strain lethal for mice in sufficient titer had not been developed. Neither had there been sufficient

Dr. Andrews, director of the National Institute of Allergy and Infectious Diseases, was requested by the director of the National Institutes of Health, Public Health Service, to act as the focal point for all of the Institutes' activities concerning influenza.

time to develop information as to what constitutes an adequate level of antigenicity as demonstrated by such a test. In these circumstances, it was decided that since chicken cell agglutination (CCA) units per milliliter are related to antibody response, Asian strain influenza vaccine would be released on CCA values alone. This necessitated the development by the division of a CCA reference standard, which was furnished all manufacturers. It was then necessary for the professional staff of the division to work closely with the technical staffs of industry in order to standardize techniques and obtain uniform results in the performance of this test.

While vaccine continued to be released during the emergency on the basis of CCA values alone, efforts continued on the development of a mouse-adapted Asian strain and of a standard reference vaccine. By mid-August such a strain was developed and was furnished the manufacturers for trial potency tests in mice. By mid-November, when the production cycle of monovalent Asian strain vaccine was nearing conclusion and a return to production of a polyvalent vaccine was near, the division had developed and given the manufacturers a standard reference vaccine containing the Asian strain. On December 1, 1957, it was, therefore, possible to require again that potency determination be based upon the same antigenicity tests in mice as were required for all influenza vaccines prior to July 1957.

NIAID Projects

Scientists at the National Institute of Allergy and Infectious Diseases have a well-established and time-honored record of research activity on respiratory ailments, including influenza. Their current interest in the latter has resulted (a) in the development of a hemadsorption-tissue culture technique which facilitates and expedites the recognition of type A influenza virus (1), and (b) in the demonstration, by means of live-virus challenge experience in human volunteers, that the Asian influenza vaccines available in July 1957 conferred definite but not complete protection against infection and reduced the severity of infection (2).

For several years, studies of the characterization and epidemiology of viral agents have been conducted in three local orphanages or homes for children. In these institutions new respiratory and enteric disease agents are being introduced by newcomers and transmitted continually within the closed populations. Periodically, inmates are systematically sampled for pathogenic microbiota on arrival and during and after clinical episodes. Thus, it has been possible to follow with considerable precision the entrance, spread, and departure of specific microagents of disease. It was assumed in advance that these institutions would be invaded by Asian strains of influenza. Plans were made and are now being implemented for determining the epidemiological patterns of influenza outbreaks and the relation and significance to influenza of complicating disease agents under conditions of different levels of vaccination. The etiology of all severe and fatal cases will be studied intensively with particular reference to antibiotic-resistant bacteria.

Cases of unusual interest will be admitted to the Clinical Center for more sophisticated clinical investigations and determinations than are possible elsewhere.

Limited studies on pregnant women and infants are also under way at hospitals in the metropolitan Washington area. Hemagglutination antibody responses and local and systematic reactions to 1.0 ml. subcutaneous injections of 200 CCA units Asian strain vaccine are being evaluated in 51 women vaccinated during the 36th week of pregnancy. Their infants will be examined at delivery for hemagglutination inhibition antibodies. Some 30 newborn babies have been vaccinated with 0.1 ml. of 200 CCA units Asian strain vaccine, half of them subcutaneously and the rest intradermally. They, too, are being followed in order to detect antibody responses and reactions.

The National Advisory Allergy and Infectious Diseases Council at its meeting on June 27-28, 1957, exhibited lively interest and concern in the impending epidemic. The council unanimously affirmed a resolution proposed by its Ad Hoc Committee on Influenza emphasizing the moral obligation of the council to make available the means for studying the diagnostic,

clinical, epidemiological, therapeutic, and prophylactic aspects of the prospective epidemic. The council recommended to the Surgeon General that the national supply of reagents needed for the diagnosis of influenzal and complicating disease agents be augmented, and that additional support be sought for extending research grants and increasing the intramural influenza investigations of the institute. It further proposed that a conference of key research personnel be called to assist in planning and designing influenza studies.

Administrative plans for implementing these recommendations were approved promptly by the Surgeon General. Funds for intramural influenza research were made available, and the sum of \$350,000 was reserved for influenza research grants. Laboratories and individuals with special interest and competence in respiratory disease study were encouraged to submit applications for research on various aspects of Asian influenza, with special emphasis on staphylococcal complications, and on evaluative studies of antibiotic prophylaxis against post-influenza pneumonia in high-risk patients, as recommended by the Public Health Service Influenza Research Committee. Some 40 requests for \$618,566 were received and reviewed promptly by the Microbiology Study Section and the National Advisory Allergy and Infectious Diseases Council. Of these, 13 for \$187,347 were approved for immediate payment. Subjects of investigation include serologic diagnostic technology, clinical aspects, therapy, basic viral studies, vaccine effectiveness under varying conditions of concentration and injection, complicating agents and conditions, etiology and virulence, epidemiology in community and institutional populations, and establishment in lower animals.

Heart Research Grants

At its meeting on June 20-22, 1957, the National Advisory Heart Council, recognizing the opportunity for studying some of the unsolved problems presented by the 1918-19 influenza epidemic concerning sudden, unexplained collapse and death, suggested that cardiovascular studies relating to influenza be encouraged. On July 12, 1957, a group of medical specialists

was convened to discuss and advise regarding specific areas of research which should be supported. As the result of recommendations of this group, the council subsequently reserved \$250,000 for special research grants for cardiovascular-renal studies of influenza and approved the establishment of a four-member Ad Hoc Committee on Influenza Studies under the chairmanship of Dr. George E. Burch, to stimulate, review, and make recommendations regarding grant requests.

This committee has recommended and the council has approved 6 research grants, 2 with supplements, in the prescribed subject area, committing \$70,840.

NIMH Projects

The National Institute of Mental Health has joined with the Health Emergency Planning Unit of the Office of the Surgeon General, the Division of General Health Services of the Bureau of State Services, and the Army Chemical Corps in a cooperative study of the impact of influenza epidemics on community life.

The mental health and health educational authorities are interested in ascertaining group behavior, panic reactions, individual and mass motivations in the face of severe epidemics, and the capability under these conditions of the local government and voluntary groups of adapting their activities to cope effectively with the situation. The emergency planners want to determine the special health needs which must be met during unsuppressed outbreaks of disease, and the Army Chemical Corps is interested in ascertaining the levels of disability and absenteeism at which essential community services fail.

It is planned to hold periodic interviews with members of randomized samples of households in 3 cities of about 50,000 population in Pennsylvania and 2 more in North Carolina. Initial baseline data have already been obtained. Special contacts will be maintained with community health personnel, including physicians, nurses, and pharmacists as well as local health department representatives. The study will include similar consideration of transportation, communication, police and fire protection, school and industrial absenteeism, industrial

productivity and costs during epidemic conditions, accident rates and other circumstances and events reflective of the stresses, failures, and compensatory counteractions which occur during epidemics.

The National Institute of Mental Health has made a grant of \$50,000 to a professional information-collecting agency which is conducting the weekly family interviews. Another \$50,000 has been contributed by the Army Chemical Corps to help defray the costs of this research. Professional skills and services valued at \$35,000 are being supplied by the Bureau of State Services for the direction, coordination, and analysis of this study.

Study of Vaccination Results

From September 3 to October 26, the Employee Health Service Branch at the Clinical Center of the National Institutes of Health offered Asian strain influenza vaccine to employees of the Institutes desiring vaccination.

Careful individual records have been maintained of the manufacturer, lot number, and concentration of the vaccine administered to each person. From subsequent reports of reactions, absenteeism, and the occurrence of influenza-like illness, it is hoped that information will be obtained on the frequency and severity of reactions and the relative effectiveness of the two concentrations of the vaccine in preventing lost work days due to influenza.

Some 6,000 adults of both sexes are involved, about 4,000 of whom were vaccinated subcutaneously at the Employee Health Service with material containing 200 or 500 CCA units. The nonvaccinated group is being sampled to determine the proportion vaccinated outside the clinical center. If this number is sizable, a survey will be made to separate the vaccinated from the nonvaccinated employees.

NINDB Projects

Knowledge of the well-established etiological role of certain filtrable agents, such as rubella and salivary gland virus, in congenital defects and abnormalities, led the National Institute of Neurological Diseases and Blindness to consider supporting extramural studies to determine whether or not influenza virus also may

cause prenatal anomalies, especially of a neuropathic type. On November 16, 1957, a meeting of advisers was held at the National Institutes of Health to discuss plans and procedures for testing this hypothesis.

The group recommended that pregnancies be followed at large obstetrical services to find out whether prenatal abnormality rates were significantly higher if influenza occurred during pregnancy, especially in the first trimester. It was assumed that evidence of prenatal abnormality, including abortion, stillbirth, and fetal and neonatal malformations and anomalies, would be provided by the attending obstetricians, pathologists, and pediatricians. It was concluded that diagnoses of influenza could be made satisfactorily on the basis of standardized serologic tests supported by clinical evidence and certain knowledge that influenza was epidemic in the community when the respiratory illness occurred. The group advised that serum specimens be obtained from the pregnant women at least at registration or the first prenatal visit, at delivery, and, desirably, shortly after convalescence from any upper respiratory episode with fever. Conclusions regarding valid associations of influenza and prenatal anomalies would be based on carefully controlled statistical correlations.

In order to simplify and expedite supplementary financing for this study, it was agreed that these observations should be made, as far as feasible, at the five hospitals where NINDB cerebral palsy project collaborative studies are being made. Other institutions may be invited to cooperate later if additional data are required. The institute will act as the collecting and coordinating agency in handling and analyzing the pooled data.

Support of these studies is expected to be by contract during the initial phase of the project, later by research grants if feasible and indicated. Initiating expenses will probably not exceed \$50,000. A large proportion of the total costs will be borne by the cerebral palsy project, of which these investigations are an integral part.

Research Committee Contributions

The Public Health Service Influenza Research Committee was established on September

26, 1957, in response to a recommendation made to the Surgeon General by the State and Territorial health officers at the special conference on influenza held August 27-28. The committee chairman is Dr. Colin M. MacLeod and there are 14 members. The purposes of this committee are (a) to review influenza research conducted or supported by the Public Health Service and other Federal organizations, (b) to identify areas where current research on influenza is lacking or deficient, and to make recommendations regarding more adequate coverage, and (c) to act in a liaison capacity between influenza research workers in or supported by the Public Health Service and those in or supported by other Federal agencies.

At its first meeting, held September 27, 1957, the committee heard and discussed detailed reports of various representatives of groups engaged in or planning research on influenza in 1957-58. On the basis of these presentations, the committee was able to identify areas of subjects in which more work should be undertaken. These included (a) the standardization of hemagglutination inhibition test reporting and methods of determining CCA values of vaccine, (b) assessment of the stability of Asian influenza vaccines in terms of CCA unit values, (c) animal tests for the antigenicity of these vaccines, (d) the efficacy of intracutaneous vaccination, (e) data concerning bacterial complications, especially staphylococcal, (f) clinical management of influenza patients with complicating infections or conditions, (g) controlled studies of Asian strain vaccination in patients with chronic pulmonary and cardiac diseases, (h) possible use of attenuated live virus influenza vaccines, (i) effectiveness of available vaccines in protecting against natural infection with Asian influenza virus, and (j) problems of vaccinating children against this strain of influenza.

The committee recommended that (a) the Public Health Service make adequate funds available as soon as possible to collaborating, nongovernmental laboratories for utilizing their resources in a collaborative study on epidemic influenza on a nationwide basis, (b) the National Institute of Allergy and Infectious Diseases use remaining reserved influenza research grant funds for studying staphylococcal

complications of influenza, and (c) the Communicable Disease Center supply on request information concerning laboratories in the United States willing and able to provide reference staphylococcal typing service.

A Subcommittee on Therapy and Management of Asian Influenza and Its Complications was formed with Dr. George E. Burch as chairman. This was co-sponsored by the American Medical Association through its Committee on Influenza. A meeting of the subcommittee was held in New Orleans on October 29, 1957. The extent and pattern of the epidemic and of associated mortality was reviewed. Information was presented and discussed concerning the more common clinical manifestations and serious complications. The following recommendations were made and transmitted to the Public Health Service Committee on Influenza Research:

1. High-risk influenza patients—that is, those with chronic cardiac or pulmonary disease, persons over 60, and pregnant women—should receive prompt and adequate therapy at the first sign of influenza.

2. Grants should be stimulated for controlled studies to evaluate in high-risk patients the prophylactic administration of antibiotics (erythromycin and chloramphenicol advocated) or other chemotherapeutic agents to prevent complicating bacterial pneumonia.

3. An ad hoc committee should be appointed on pneumonia and deaths associated with Asian influenza to establish standard clinical, microbiological, and pathological criteria for determining influenza association, etiology of pneumonia, and cause of death, and to compile the results of applying these criteria during the current epidemic year.

4. Numerous small clinical studies should be made of the pathological physiology, course, and management of Asian influenza.

5. Serious consideration and long-term support should be given to research on the acute infections in people of middle age or over, studies being made to determine physiological and biochemical alterations to be derived therefrom.

The committee emphasized need for thorough and early diagnostic procedures, particularly chest X-rays, in persons presenting pro-

longed and complicated courses following influenza.

films

"For the Nation's Health"

16-mm. filmograph, color, sound, 15 minutes. 1957.

Audience: Personnel in the health, medical, and allied professions, students, parents, teachers, counselors, civic groups, and the general public.

This Public Health Service orientation film presents a panoramic view of the activities of the principal health agency of the Federal Government. Combining photographs and motion picture film, it shows the growth of the Public Health Service from its inception in 1798, with limited care of sick and stranded merchant seamen, to its farflung programs today in hospital and medical care, in medical and biological research, and in public health.

Physicians, nurses, dentists, sanitary engineers, pharmacists, veterinarians, and a host of other skilled specialists are shown at work at home and abroad.

In Public Health Service hospitals and clinics, in well-equipped laboratories, on Indian reservations and other field assignments, and on Coast Guard duty, the range and variety of the work of the Public Health Service rarely fails to arouse interest.

Public Health Service personnel have been notified that the film is available to them, principally for

training and orientation purposes, through the Communicable Disease Center, Public Health Service, 50 7th Street NE., Atlanta 5, Ga.

Others interested and Service personnel also may order the film on a short-term loan from the Surgeon General, Public Health Service (P), Washington 25, D. C. The filmograph may be purchased from Byron, Inc., 1226 Wisconsin Avenue, Washington 7, D. C. Cost of the print, \$62.07, includes reel can, shipping case, and service charge.

Backsiphonage and Cross Connections: An Introduction

35-mm. filmstrip, color, sound, 11 minutes, 75 frames, 1957.

Audience: Sanitarian trainees and other public health personnel, including food handlers, and custodial and dining car personnel.

Many plumbing systems suffer from defects in design and installation. Backsiphonage and cross connections, two such defects, are both potential sources of waterborne disease epidemics.

This series of graphics, cleared for television, illustrates the significance to public health of backsiphonage and cross connections, tells how to identify the basic causes, and shows the methods of prevention. It surveys the major situation in which the two defects occur.

This filmstrip may be obtained on loan from the Communicable Disease Center, Public Health Service, 50 7th Street NE., Atlanta 5, Ga., or

by purchase from United World Films, Inc., 1445 Park Avenue, New York 29, N. Y.

Public Health Problems In Mass Evacuation

16-mm. film, black and white, sound, 13 minutes, 462 feet. 1957.

Audience: Civil defense trainees in all phases of public health, schools, PTA groups, civic club members, and television viewers.

Mass feeding of evacuees poses serious public health problems

This motion picture showing public health problems attending the mass evacuation of an urban population emphasizes the magnitude of such problems as mass feeding, water supply, medical care, waste and sewage disposal, consequent disease outbreaks. Its objective is the motivation of discussion rather than the solving of problems.

This film may be obtained on loan from the Communicable Disease Center, Public Health Service, 50 7th Street NE., Atlanta 5, Ga., or by purchase from United World Films, Inc., 1445 Park Avenue, New York 29, N. Y.

The R. E. Dyer Lecture

Influenza

History, Epidemiology, and Speculation

RICHARD E. SHOPE, M.D.

WE ARE FACED at the moment with the most publicized influenza epidemic of all time, and there is great diversity of opinion concerning its eventual course and outcome. Some, who believe that the present outbreak is no different from those that have appeared periodically since the 1918-20 pandemic, contend that it will come and go without any serious effects and that the public is being unduly alarmed. Others feel that the present outbreak

Dr. Shope is professor and member of the Rockefeller Institute for Medical Research, New York City. With a special interest in pathology, he has made important contributions through his investigations of such subjects as swine influenza, epidemiology of virus diseases, and intermediate host systems in infectious diseases. The latest among his many honors is a 1957 Albert Lasker award, conferred on him for outstanding achievement in research on infectious diseases. Currently, Dr. Shope is also director of the Armed Forces Commission on Epidemiological Survey.

bears some of the earmarks of the epidemic illness that occurred in the spring preceding the great influenza pandemic of the autumn of 1918 and that, as such, may constitute but the first wave of a more serious type of influenza to follow. Those who consider that this speculation may have some probability believe that the time has arrived when we must attempt to determine whether our knowledge of influenza is advanced enough to permit a serious attempt at combating it or whether we are still in a phase where all we can do is conduct further studies of pandemic influenza. The latter group are of the opinion that an intensive program of widespread immunization with a vaccine containing the new influenza virus strain should be instituted with all possible promptness.

The current epidemic of Asian influenza apparently started late in February of 1957 in Kweichow Province in southwest China. It spread to Yunnan Province in early March and was fairly well distributed through China by the end of that month. It spread to various

parts of the Orient during the following 3 months and reached the United States about the middle of May.

In this country, the disease spread slowly, involving initially military establishments that had received personnel returning from the Orient. It appeared in various groups of civilians that congregated from different parts of the United States during the summer, most notably in summer camps and in a summer church conference at Grinnell, Iowa. Ill individuals returning from these meetings set up foci of infection in their home communities, and by late July and early August the disease was widely seeded throughout the United States. During the early part of the outbreak, Asian influenza showed little tendency to spread except on very close contact and tended to remain sporadic. With the beginning of autumn, the disease diffused more widely and rapidly than it had at first (1).

The symptoms shown by individuals ill with influenza, consisting of fever, depression, anorexia, and variable respiratory signs, have been relatively mild and have lasted for 2 to 5 days. There have been to date relatively few deaths attributable to Asian influenza.

Asian influenza has as its primary etiologic agent a type A influenza virus which appears, on serologic grounds, to be antigenically quite different from type A influenza viruses that have prevailed in previous outbreaks, swine, A, and A' (2). It would appear from this that the world is being exposed to a virus with which it has had little or no previous experience and that, theoretically at least, we should be ripe for an extensive outbreak with the new agent.

The marked antigenic shift in the Asian virus, the deficiency of antibody against it in humans, and its relatively rapid spread and high attack rates in the Far East are features of the new virus that alarm many people. In addition, a number of the deaths that have occurred in our country have been in young adults, the age group that was hardest hit during the devastating 1918-20 outbreak. The suggestion from all this is that the current influenza virus has epidemiological and pathogenic potentials that must be taken seriously.

To lay groundwork for speculation about the possible course and outcome of the present out-

break of so-called Asian, or Far East, influenza, I should like to review briefly a little of what is known of past influenza pandemics. No one knows when pandemic influenza first appeared, although Hirsch (3) dates its initial recognition to the year 1173. Since then it has recurred at irregular intervals under various names: febris catarrhalis epidemica, tussis epidemica, and finally influenza. The most recent pandemic, that of 1918, was by far the most deadly ever experienced. During the 4 autumn months that it prevailed, it caused some 21 million deaths throughout the world. Nearly half a million of these occurred in the United States. Thus almost three times as many people died of pandemic influenza as lost their lives during the 4 years of World War I, which ended just as the 1918 pandemic was passing its peak.

I have selected three outbreaks of pandemic influenza to discuss, for comparative purposes, and to use historically in connection with my consideration of the present influenza outbreak. I have chosen one from olden days, before the speed of modern travel entered to confuse the epidemiological picture (1789), one from the beginning of the bacteriological era (1889), and one modern one (1918).

Pandemic of 1789

The 1789 outbreak of influenza as it occurred in the United States was well described by Robert Johnson in his inaugural dissertation for the degree of doctor of medicine at the University of Pennsylvania in 1793. To orient you as to the time of this influenza outbreak, it came in the year that Washington was inaugurated President, that the first Congress met in New York, and that the French Revolution began. The first steamboat did not cross the Atlantic until 1819, and the first steam train did not run until 1830. Air travel, of course, was not even dreamed of. This outbreak occurred before modern means of rapid travel were available and when a man could go no faster than his horse could gallop. Despite this, according to Johnson, the influenza of 1789 spread like wildfire. It had the usual earmarks of later pandemics, being characterized by a prostrating illness of sudden onset and a febrile course of 4 to 5 days. Recovery was followed by several weeks of per-

Pandemic and Interpandemic Influenza

The term "pandemic" is ordinarily applied to a disease affecting or attacking all or a large portion of the population of a region: a disease extensively epidemic. Nothing in the usual definition of the term implies degree of severity. However, in current influenza parlance, the word "pandemic" has acquired a connotation of severity as well as extent of distribution. In this lecture pandemic designates a severe type of influenza such as that occurring in 1889 and during the autumn of 1918. The term "interpandemic influenza" denotes the milder type occurring between the pandemics at roughly 2-year intervals or oftener.

sistent coughing and prolonged debility in some instances. The attack rate was high, and the disease affected mainly persons in middle life.

The mortality rate was low, according to Johnson, and most patients recovered unless injudiciously treated. The suggestion was apparent in Johnson's paper that the treatment might frequently be more hazardous to life than the disease itself.

Now Johnson, in his definition of influenza, characterized it, among other things, as "a disease capable of being propagated by contagion." In spite of this conception, he could not completely rationalize the speed of its dissemination on the basis of transmission by contagion alone and visualized the importance of a "vicious quality of the air."

Johnson supported his contention about the spread of influenza by citing examples from the pandemic of 1782, in which he felt transmission by contact did not play the essential role. He stated, "Influenza appeared at London between the 12th and 18th, at Oxford in the third week, and at Edinburgh on the 20th day of May." He doubted that the disease could have been transferred to these three cities in such rapid succession "by things imbued with the contagion or by persons labouring under the complaint."

Later in his thesis he wrote, "On the 2d day of May 1782, the late Admiral Kempenfelt sailed from Spithead with a squadron under

his command, of which the Goliath was one, whose crew was attacked with the influenza, on the 29th of that month: the rest were affected at different times: and so many of the men were rendered incapable of duty by this prevailing sickness, that the whole squadron was obliged to return into port about the second week in June, not having had communication with any shore, and having cruised solely between Brest and the Lizard."

Still another example was cited as follows, "About the 6th of May [in the same year 1782], Lord Howe sailed for the Dutch coast, with a large fleet under his command: all were in perfect health: towards the end of May the disorder first appeared in the Rippon, and in 2 days after in the Princess Amelia. Other ships of the same fleet were affected with it at different periods: Some indeed not until their return to Portsmouth about the second week in June. This fleet also had no communication with the shore until their return to the Downs, on their way back to Portsmouth, towards the 3d or 4th of June."

Johnson rationalized his views concerning the multiplicity of foci of origin of influenza during a pandemic by contending, "The morbid matter exciting the disease must have originated at some time and somewhere: and a cause like to that which gave rise to it in any one country, at any one point of time, might produce it in another country at the same time, under similar circumstances."

He continues, "I do not assert, nor do I wish to be understood to mean, that the influenza is not at all contagious: on the contrary, I am possessed of facts which prove in the most incontestable manner, that it may be, and often is, propagated from one person to another by means of contagion. But I mean, and the arguments which I have adduced, I trust, will warrant the conclusion, that the disease often does arise from some vicious quality of the air, or exhalation in it, as well as from a matter arising from the body of a man labouring under disease."

It is apparent that Johnson had certain difficulties in understanding and explaining the rapidity of spread of influenza. However, he did not have to make his views take into account the knowledge that influenza is an infectious

disease with a specific microbial cause, but instead could implicate various meteorologic abnormalities to explain incongruities that were beyond his comprehension.

I have gone into some detail in outlining opinions and observations concerning a pre-modern pandemic of influenza because I wanted to point out that influenza spread with unbelievable rapidity even before we had fast transportation to blame for its rapid and widespread diffusion and that, in the absence of such explanations to account for its dissemination, others, plausible at the time, were resorted to.

Pandemic of 1889-90

The first pandemic of influenza in the bacteriological era was that of 1889-90. Finkler (4) has written, ". . . this influenza epidemic broke forth from the East, and overwhelmed the world in a pandemic such as had never before been seen. The high flood of the pandemic flowed over the whole globe in the space of a few months." It started supposedly in Bukhara in Turkestan in the month of May, though influenza was also prevalent in Greenland and in Hudson Bay territory at about the same time. Influenza did not become widespread in 1889 until October, when it prevailed over most of Siberia and European Russia. There it was supposedly first confused with dengue and later referred to as Siberian fever. By November it was prevalent over most of the rest of Europe, and in December was widespread in England and America. In the United States, the disease raged for about 2 months before subsiding, and there were periodic recrudescences during the next 4 years (4, 5).

There seems to be general agreement that this pandemic had most of the characteristics of the greater one in 1918 except for its lower fatality. W. T. Vaughn (6), who studied the 1918 pandemic and thoroughly reviewed the literature dealing with that of 1889, wrote in his monograph on influenza, "The longer one studies the observations made in 1889-93, the more firmly convinced one becomes that the recent pandemic (1918) was identical with the former in practically all of its manifestations."

The main finding of value from the studies of the influenza pandemic of 1889-90 was the discovery by Pfeiffer of the so-called influenza bacillus (7). Pfeiffer believed that this organism was the cause of influenza because, according to him, it was present in all cases and not present in normal individuals unless they had recently recovered from influenza. Furthermore, it was associated with the lesions of the disease. Pfeiffer's views were widely accepted, and it is safe to say that the majority of medical people at the time believed that he had discovered the cause of influenza.

The 1889 pandemic may turn out to be of especial interest in connection with the current outbreak of influenza. Studies of the antibody content for the Far East strain of influenza virus in serum samples from persons of various ages have resulted in some very unusual and interesting findings: it has been noted that only samples from individuals 70 to 90 years old contain antibodies for this new virus (8, 9). This finding may date the time of last occurrence of a virus of the serologic type of the present Asian strains, and the age distribution comes suggestively close to placing the time in the neighborhood of the 1889 pandemic. Thus there seems to be a possibility that we are at the moment experiencing a revisitation of the 1889 pandemic strain of influenza. This is, of course, speculative.

Pandemic of 1918

During the spring of 1918 an influenza-like disease became prevalent in various parts of the world. This spring outbreak has been generally accepted as the first wave of the great 1918 pandemic. It is believed by epidemiologists to have been the immediate forerunner of the severe autumn outbreak which swept through the entire world with such deadly effect (6).

The first wave in 1918 received especial prominence in Spain, where it was said to have been sudden in its appearance and brief in its course, and to have subsided without leaving a trace. During April an illness similar to the Spanish epidemic occurred in American, British, and French troops in France, as well as in the civilian population. In England the first wave appeared in June and was composed for the

most part of mild cases (10). It affected simultaneously a large percentage of the population and showed a preference for individuals between 15 and 35 years of age. An influenza epidemic occurred also in Japan and China in the spring of 1918 (11). It was mild and was variously called "3-day fever" or "wrestler's fever," in addition to influenza. The spring wave of influenza was not highly diffusible; it reached only limited regions of Africa, largely missed South America, and affected Canada only slightly.

It is evident from accounts of the first wave that it was almost everywhere very mild so that although the morbidity was often high, sometimes amounting to 50 percent or more of the invaded population, the case fatality was exceedingly low (10). In many localities the general mortality rates were scarcely affected. In most countries the total number of persons contracting influenza seems to have been considerably smaller in the first wave than in the second.

The second wave, which proved to be extremely lethal, struck simultaneously in many parts of the world. It is generally stated to have appeared in Europe during the last week in August. In the United States it appeared first in Boston, supposedly from cases occurring on the receiving ship at Commonwealth Pier, during the last week of August also. During the next week it broke out among troops at Camp Devens in Massachusetts and sailors at the Great Lakes Naval Training Station in Illinois. Between the first and middle of September, hundreds of new foci appeared in various army camps, naval stations, and civilian communities. By the first week in October the pandemic was full blown throughout the entire world with the exception of a few islands and Australia. The height of the pandemic so far as this country is concerned was the fortnight between October 12 and 26 (6, 10).

In the second wave, although there were many cases of the same mild type as in the first, perhaps as many as 80 percent of all attacks, a different manifestation of disease became prominent. This took two forms: (a) cases which started immediately with an acute pulmonary inflammation resulting in lung edema, violet cyanosis, and death within a few days,

and (b) cases which developed on the fourth or fifth day of an ordinary influenza a definite bronchopneumonia which ran the usual course of primary bronchopneumonia of prepandemic times and was followed, accordingly, either by death or by a long convalescence (12).

Despite the fact that there was some divergence of opinion and considerable confusion concerning the epidemiological data, most epidemiologists believed that the 1918 autumn pandemic arose at 1 or 2 sites and from these spread throughout the world in a little over a month's time. It was commonly accepted, and there was evidence to support the opinion, that the pandemic in this country started in or near Boston (6, 10). The cases responsible for the infection in Boston supposedly came from Europe, where the pandemic got under way very little, if any, earlier than it did in the Boston area. The infection was said to have been spread to other parts of the United States by the movement of patients among the civilian population or by the transfer of infected military personnel from one camp to another. The speed of spread was accounted for on the basis of the speed of available transportation. Certainly in a large number of instances, cited in the literature of the times, the onset of the disease in a community or a military establishment coincided very closely with the arrival of infected individuals.

However, certain discrepancies enter to spoil the perfection of the case-to-case transfer explanation for the spread of influenza during the second wave of the 1918 pandemic. These have to do with certain flukes in distribution, certain skips of large bodies of population. For example, Boston and Bombay had their epidemic peaks in the same week, while New York, only a few hours by train from Boston, did not have its peak until 3 weeks later (10). In like manner, Seattle, Los Angeles, and San Francisco had their epidemic peaks some 2 weeks earlier than Pittsburgh, which is just an overnight run from the infected eastern seaboard cities. In some respects, the epidemiologist had an easier time getting the pandemic disease transferred over long distances than in taking it to communities nearby. Thus, though it got to Chicago, presumably from Boston, fairly early and affected that city in September, it did

not reach Joliet, just 38 miles away, until October. Similarly, it took 3 weeks to cross the little State of Connecticut from New London County to Fairfield County (10).

In the light of these various epidemiological ambiguities one cannot help wondering whether perhaps more than one mechanism of dissemination may have been operating during the 1918 pandemic to account, on the one hand, for the lightning-like spread of disease over large distances and, on the other hand, for its slower diffusion over relatively small distances. The suggestion is apparent that extensive and widespread preseeding of virus in a masked or occult form, with its almost simultaneous provocation to infectivity by a stress common to wide geographic areas, might better account for the appearance of extremely rapid dissemination over great distances than does the view that case-to-case transfer was the responsible mechanism.

In swine influenza, a disease that I shall discuss a little later, the causative virus is preseeded in a masked, noninfective form by means of an intermediate host, the swine lungworm (13). Swine preseeded in this manner with occult virus remain normal to all outward appearances. However, all that is required to bring them down with influenza is the application of some stress of itself relatively innocuous. The stress, operative in nature for swine influenza, is meteorologic in character and is associated with the onset of cold, wet, inclement weather in the autumn (14). Swine that have been preseeded with masked influenza virus come down almost simultaneously in geographically widely separated areas when subjected to the same meteorologic stress, and the resultant widespread outbreak of influenza creates the illusion of being a disease that has diffused over an extensive area with unbelievable rapidity (15). Secondary cases of swine influenza follow at a more leisurely pace as a result of case-to-case contact with the primary, provoked infections.

I do not mean to imply, of course, that during the 1918 pandemic, the swine lungworm preseeded influenza virus in the human population. What I should like to suggest, though, is that influenza virus may be capable of existing in a masked form, similar to that found in

the swine lungworm, in the human respiratory tract and that in such form it may be widely preseeded throughout a human population. It seems possible even that such preseeding may have been one of the functions of the milder, more slowly diffusing first wave of the 1918 influenza pandemic.

To return to further consideration of the 1918 pandemic, it may be said that, despite the apparent epidemiological discrepancies to which I have called attention, the opinion that direct and indirect transmission from man to man could account for the observed epidemiological picture of pandemic influenza was generally accepted. Whatever the correct explanation may be for the wide dissemination of the 1918 autumn pandemic, there is no doubt that the disease became very extensively distributed in short order. This second wave differed from the first in that it was more severe, more widespread, of greater dispersive power, and in some places at least, of a different age incidence.

The mortality rates recorded during the second wave varied widely among different groups and communities. The case fatality rate ranged from 3.1 percent in New London, Conn., to 0.8 percent in San Antonio, Tex. (16). Military personnel were especially hard hit, and Vaughn and Palmer (17) have stated that during the 4 autumn months of 1918, 1 of every 4 soldiers in the United States had influenza, 1 of every 24 developed pneumonia, and 1 of every 67 died.

Efforts to Prove Contagiousness

With all of the observed clinical and epidemiological evidence pointing to the likelihood that the 1918 pandemic influenza was highly contagious and spread from sick to well easily and apparently at the very first available opportunity, one would have anticipated that proof of its contagiousness by transmission tests in human volunteers would have been extremely easy. However, such did not prove to be the case: in not a single controlled experiment was it possible to demonstrate the transmissibility of the disease.

The most carefully planned and conducted experiments were those carried out by the Navy and the Public Health Service. In the series

of experiments conducted in Boston during November and December 1918, 62 volunteers between 15 and 34 years of age were used (18). Thirty-nine of these had no history of having had influenza at any time, although apparently some degree of exposure had occurred. Filtered and unfiltered secretions from the upper respiratory tracts of patients with typical influenza were sprayed into the nose and throat and instilled into the eyes of some of the volunteers; direct swabbing from nasopharynx to nasopharynx was the method of exposure for others; and in one experiment freshly drawn citrated blood was injected subcutaneously. The results were summarized as follows: "In only one instance was any reaction observed in which a diagnosis of influenza could not be excluded, and here a mildly inflamed throat seemed the more probable cause of the fever and other symptoms. Nothing like influenza developed in the other volunteers."

In an attempt to imitate nature more closely, 10 volunteers were exposed to patients with acute influenza in hospital wards. Each volunteer was placed very near the patient, shook hands with him, chatted with him for 5 minutes, and then received the patient's breath full in his face five times while he inhaled. Finally the patient coughed five times directly in the subject's face. Each volunteer did this with each of 10 different patients, all of them acutely ill for not more than 3 days. All patients used had typical acute cases selected from a distinct focus or outbreak of disease. None of the volunteers developed the disease.

A second series of similar experiments was carried out in San Francisco during the same period also with completely negative results (19).

These two groups of experiments were considered to show that the requirements for the transmission of influenza from man to man, such as apparently exist commonly under natural conditions, are not readily imitated experimentally. Actually they constituted probably a very good demonstration of how solid an immunity was conferred by even a subclinical bout with the etiological agent of the 1918 influenza.

Much work was expended during the 1918 pandemic in an effort to determine the causative agent of the outbreak. Prior to the 1918

studies, *Hemophilus influenzae* had been generally regarded as the agent responsible for influenza. It seems quite natural, therefore, that much of the 1918 investigative work should have been concerned with a further study of the relationship of this bacterium to the disease. The results obtained were frequently confusing and contradictory, which is not surprising in view of the fastidious character of the organism and the technical difficulties associated with its isolation from the respiratory tract. It is difficult to give an accurate appraisal of the significance of the large amount of work done during the 1918 pandemic in trying to prove or disprove the etiological relationship of the Pfeiffer bacillus to influenza. About all that can be said is that the role of the organism was more controversial after the smoke of the 1918 pandemic studies had cleared than it had been before.

With the failure to gain clear-cut evidence that *H. influenzae* was the cause of the 1918 pandemic, the view was rather widely held and was frequently expressed that a virus was probably the etiological basis for the disease. This actually constituted no more than an ungrounded opinion, for consideration of the data on the subject published from 1918 investigations reveals that no one adduced good evidence to incriminate a virus as the causative agent. The upshot of a terrific amount of effort during the 1918 influenza pandemic to learn the cause of the disease was to weaken the view that Pfeiffer's bacillus was the etiological agent and to substitute no other in its place.

I have just indicated that no one succeeded in determining the causative agent responsible for the 1918 pandemic influenza. This is not strictly true and what I should have said is that no investigator working in a laboratory did it. Actually Mother Nature stepped in and took care of the situation for us, as I shall now point out.

Swine Influenza

At the height of the second wave of the 1918 pandemic, a new disease appeared among swine in the Middle West. This new disease was not a sporadic and localized outbreak; actually millions of swine became ill and thousands died

during the first few months of its occurrence. The epizootic persisted in various localities until January 1919 and reappeared in the autumn and winter of that year as extensive and severe as in 1918. It has recurred each year since then, but it varies annually in its severity and extent.

Dr. J. S. Koen, an inspector in the Division of Hog Cholera Control of the U. S. Bureau of Animal Industry, was the first to recognize that the disease was different from any previously encountered (20). He was so much impressed by the coincidental prevalence of human influenza and by the resemblance of the signs and symptoms seen in man to those occurring in hogs that he became convinced that the two were actually the same. He therefore gave the name of "flu" to this new disease of hogs. The opinion of Koen that "flu" represented an entirely new swine epizootic disease and that swine might have been infected in the first instance from man was shared by some veterinarians and many farmers in the Middle West (21).

Everything was not rosy, however, with Koen's contention that a direct causal relationship might exist between the swine and the human diseases. The basis for the objections was largely economic since it was feared that, if it became widely known that swine could acquire human influenza, the pork-consuming public might become alarmed and the pork market would be adversely affected. Koen, however, was a fiery little man and, though frequently forced to defend his convictions verbally, stuck to them steadfastly. A year after his choice of what seemed a most unpopular name and diagnosis, he defended himself as follows (22):

"I have no apologies to offer for my diagnosis of 'flu.' Last fall and winter we were confronted with a new condition, if not a new disease. I believe I have as much to support this diagnosis in pigs as the physicians have to support a similar diagnosis in man. The similarity of the epidemic among people and the epizootic among pigs was so close, the reports so frequent, that an outbreak in the family would be followed immediately by an outbreak among the hogs, and vice versa, as to present a most striking coincidence, if not suggesting a close

relation between the two conditions. It looked like 'flu,' it presented the identical symptoms of 'flu,' and until proved it was not 'flu' I shall stand by that diagnosis."

The late Dr. Paul A. Lewis and I began our studies of swine influenza during the autumn of 1928, and we were elated and pleased when we isolated from our very first cases of the disease an organism that was, so far as we could tell, like the non-indol-producing strains of Pfeiffer's bacillus (23). We named this organism *Hemophilus influenzae suis*. We isolated the same organism from field outbreaks of swine influenza again in 1929 and in 1930. It was the only organism we found with any regularity, and sometimes it was the only one present in the respiratory tracts of sick swine. Unfortunately, so far as assigning it etiological importance was concerned, *H. influenzae suis* administered in pure culture to susceptible swine produced no illness. We were thus faced with the dilemma of having found an organism that seemed always to be present in cases of the disease, that was demonstrable at the sites of the influenza lesions in the respiratory tract, but that failed to induce disease when administered to normal swine.

It was subsequently found that a filtrable virus, differing from any hitherto known, was important in the causation of swine influenza (24). This virus, however, was not the sole cause of swine influenza: when the virus was administered alone to susceptible swine it produced a disease that was clinically much milder than the true swine influenza as seen under natural conditions.

It was finally determined that swine influenza was a disease of complex etiology and that both the bacterium *H. influenzae suis* and the new filtrable virus were etiologically essential (24). We thus had in swine influenza a disease caused by the concerted activity of two agents, one of which, the bacterium, was strikingly like Pfeiffer's bacillus, long suspected by many of playing a causative role in human influenza. The other agent etiologically essential was completely new and did not, so far as anyone knew at the time of its discovery, have a counterpart in human disease. As it later developed, however, when Smith, Andrewes, and Laidlaw (25) demonstrated a virus as the cause of an in-

fluenza outbreak in 1933 and when this new virus was compared with the one from swine influenza, the two were found to be strikingly alike. They affected the same species of animals; they gave a high degree of cross protection against each other; and they could only certainly be differentiated from one another on the basis of certain serologic tests (26-29).

Thus in 1933 we had for consideration the intriguing situation of an animal disease of complex etiology, resembling influenza, in which one of the essential agents resembled the bacterium found extensively present in the second wave of the 1918 influenza pandemic and in which the other essential agent resembled the virus responsible for the then current inter-pandemic influenza. It seemed that, despite the failure of human investigators of the 1918 influenza pandemic to discover the cause of the outbreak, Mother Nature, using swine as her experimental animals, had done so. Furthermore, she had apparently segregated not one human agent but two from the disease of the severe second wave.

The late Sir Patrick Laidlaw (30) and I (31) summarized the indirect historical and experimental evidence bearing on the relationship of swine influenza to pandemic human influenza and pointed out that it strongly indicated the likelihood that swine had indeed acquired their infection naturally from man in 1918 and that the swine influenza virus was, therefore, the surviving prototype of the 1918 pandemic virus. Two further bits of experimental evidence have subsequently been developed in support of the hypothesis. In serologic tests conducted against swine influenza virus with serum samples from humans of various ages in 1935 and 1936, the results were such as to indicate strongly that an agent of the swine influenza virus type had been widely prevalent in man in the period from 1918 to 1920 and had not been present since then (32, 33). In like manner, serologic tests conducted in 1952 (34) with swine influenza virus and the serums of humans of various ages again pinpointed the time of prevalence of an agent of the swine influenza virus type to the 1918-20 period. These two sets of studies, one carried out 17 years and the other 34 years after the 1918 pandemic, both orienting the time of prevalence of a virus of the swine influenza

type to the period 1918-20, would seem rather effectively to support the view that swine influenza represents the surviving prototype of the agent that prevailed in man during the second wave of the 1918 influenza pandemic.

In brief, it seems to me that, from the swine influenza findings, one is warranted in speculating that the second wave of the 1918 influenza pandemic had as one of its etiological components a virus that was serologically closely related or identical to the swine influenza virus. It was, therefore, a type A virus not too much unlike the type A viruses with which we have had experience in the influenza outbreaks since 1933.

I am further going to assume for speculative purposes that the etiology of swine influenza as we know it today represents accurately the etiology of the second wave of the 1918 pandemic and that back in the autumn of 1918, when swine acquired their disease from man, the pigs effectively segregated the important etiological components of the human disease, namely, Pfeiffer's *H. influenzae* and a type A influenza virus. I hope that you will not consider this last assumption too illogical because to me it appears completely reasonable that, if an experimental host can select the etiologically essential virus, it might equally well be expected to select, from the mixture of micro-organisms that prevailed during the second wave of the 1918 outbreak, the etiologically important bacterium.

Evidence of Immunity

A question of very great interest to us right now, when we are in the midst of an outbreak of mild influenza which may turn out to be the first wave of a more severe outbreak, is what constituted the difference between the mild first wave and the severe second wave of the 1918 pandemic. I have speculated, on the basis of the swine influenza work just discussed, that the second wave of the 1918 pandemic was caused by a type A influenza virus, of which the swine influenza virus is the surviving prototype, acting in concert with *H. influenzae*. What then caused the first wave, and why was the first wave so much milder than the second one? Are there any data

from the investigative work conducted during the 1918 outbreak that might shed light on the relationship of the one wave to the other? I believe that there are and that they concern the question of immunity conferred by an attack of influenza during the first wave against infection during the second.

Because this question of the presence or absence of an immunological relationship between the first and second waves of the 1918 influenza has an important bearing on my speculations, I should like to cite several examples dealing with this point.

The Annual Report of the Surgeon General of the Navy for the year 1919 says in part, "... many men of the Navy who had influenza in the spring or summer of 1918, while in European waters, escaped during the later epidemics (winter 1918-19) both in Europe and the United States. The British Grand Fleet experienced the same thing: with few exceptions those men who contracted influenza in May and June were not attacked during the more fatal epidemics in October, November, and December. The conclusion is that mild attacks earlier in the year, as a rule, conferred immunity against the more fatal type of the disease which prevailed subsequently." With regard to the experience in the British Navy, Dudley (35) has pointed out that the crews of only certain ships were affected by the first wave, the crews of others escaping the infection. During the second wave the attack rate on the ships that had had the earlier infection was about 25 percent, while on those ships that escaped the first wave the attack rate was about 50 percent.

In most Army groups the outfits were moved about too much and transferred too frequently to furnish reliable records as to an immunological relationship between the two influenza waves in 1918. There are, however, large numbers of isolated records involving relatively small numbers of individuals. For instance, Gibbon (36) writes that of 400 patients with influenza hospitalized from among the 2,000 troops under his care, none admitted in June, July, or August was readmitted in October, November, or December, and none admitted in either of those periods was readmitted in February 1919. Dopter (37) reports

recurrent epidemics in a French Army division of which he was surgeon in 1918. During the spring wave, toward the end of April, only the infantry regiment of the division was attacked, the artillery regiment escaping infection. In the fall a group of heavy artillery was attached to the division, bringing influenza with it. The disease spread, but only those not ill during the first wave were very seriously ill in the second.

V. C. Vaughn (38) cites the experiences of the 2d Infantry Regiment which underwent influenza in June of 1918 in Hawaii before being transferred to Camp Dodge about August 1. When the severe second wave hit Camp Dodge in September and October, the 2d Regiment was only slightly affected, although the attack rate for the camp as a whole was about 33 percent and the case fatality 6.8 percent.

Probably the most impressive example of immunity among troops is that related by V. C. Vaughn (39) for a division stationed at Camp Shelby. The division, numbering about 26,000, underwent a mild influenza epidemic of about 2,000 cases in April 1918. Vaughn comments as follows on the subsequent history of the division: "This was the only division that remained in this country without change of station from April until the fall of 1918. During the summer this camp received 20,000 recruits. In October 1918 the virulent form of influenza struck this camp. It confined itself almost exclusively to the recruits of the summer and scarcely touched the men who had lived through the epidemic of April. Not only the 2,000 who had had the disease in April, but the 24,000 who apparently were not affected escaped the fall epidemic. It appears from this that the mild influenza of April gave a marked degree of immunity against the virulent form in October."

Certain information about the civilian population also indicated an immunological relationship between the first and second waves of influenza. Malone and McKendrick (40) observed in Calcutta that three institutional populations who experienced infection during the July wave passed through two later waves, in December 1918 and February 1919, without contracting the disease a second time. They believed that their evidence indicated an im-

munity lasting for at least 9 months. The Inspector General of Health in Spain (cited by W. T. Vaughn, reference 6) reported that those cities that had the disease in May 1918 suffered lightly in the autumn, while cities that had been spared in the first invasion suffered most in the second. V. C. Vaughn (39) has pointed out that among the large cities in the United States having a low death rate during the autumn wave of influenza were a number that had reported an unusually high incidence of influenza and pneumonia in the spring. Jordan (10) has called attention to the fact that the attack rates in English towns during the autumn wave were only about half those prevailing in towns in the United States and comments on the temptation to account for the differences on the basis of the more sharply defined and extensive first wave which prevailed in England having conferred a more extensive immunity. W. T. Vaughn (6) in studies deriving from his house-to-house canvasses in Boston found only four instances of more than one attack of influenza among 1,971 cases occurring in his series between March 1918 and August 1919.

There are, of course, some examples in the literature which fail to show a clear-cut immunological relationship between the two waves. My reason for calling detailed attention to the examples indicating a relationship and neglecting those that do not is this: When one is seeking to show a positive relationship between two conditions of unknown etiology, a positive correlation is, because of diagnostic uncertainties, of much more value in indicating the true relationship than is a negative one.

It is apparent, I believe, from the examples I have just cited that, by and large, an attack of influenza during the mild first wave protected an individual against infection during the more severe second wave. Such a relationship strongly suggests that the etiological agents responsible for the two waves were either identical or so closely related immunologically as to cross-protect one against the other. Since what presumptive evidence we have indicates that a type A influenza virus of the swine influenza prototype was involved in the second wave during 1918, the assumption seems warranted from this immunological data that the

same or a very closely related type A virus was also involved in the first wave. Why then, since similar influenza viruses were apparently of etiological importance in each of the waves, were the two waves clinically so different?

Role of *H. Influenzae*

A possible answer to this question, I believe, is supplied by the bacteriological studies of those investigators who sought to find the Pfeiffer bacillus during both waves of the 1918 pandemic. As I have pointed out, from the time of Pfeiffer's announcement of its discovery in 1892 until 1918, *H. influenzae* was generally regarded as the agent responsible for epidemic influenza. Because of this belief, much of the work done during the 1918 pandemic was concerned with a further study of the relationship of this bacterium to the disease.

In the light of this large effort to find *H. influenzae*, the marked difference encountered in the incidence in which it was demonstrated during the first and second waves by individual investigators who studied both waves was striking and suggestive. The findings of almost all were in agreement that the Pfeiffer bacillus was either absent or of low incidence in cases of the first wave and abundantly present during the second wave. Sobernheim and Novakovic (41), for instance, found Pfeiffer's bacillus to be practically absent from the early cases, whereas in the second wave they found it in pure culture in a large majority of the cases investigated (18 out of 23). Fildes, Baker, and Thompson (42) failed to find influenza bacilli in cases during July and August but found them during the autumn wave in the sputum of 12 of 15 uncomplicated cases and in practically all their postmortem material. Similarly, McIntosh (43) failed in the summer but found Pfeiffer's bacillus in the autumn in 8 of 12 examinations of the nasopharynx in uncomplicated cases, and in the sputum of 21 of 25 cases with bronchopneumonia. The experience of others both in Europe and in the United States was similar (44-47).

In this country, for example, Opie, Blake, Small, and Rivers (47) found that the incidence of Pfeiffer's bacillus in normal individuals from isolated communities, or in groups free from respiratory disease prior to the occur-

rence of the 1918 autumn epidemic, was relatively low (10 to 20 percent), but that before the fall epidemic, in groups in which bronchitis and pneumonia were fairly prevalent, the incidence was higher (25 to 50 percent). During the epidemic the incidence rose to 95 percent.

I believe it can be safely said that, so far as the bacteriology of the first wave of the 1918 influenza epidemic can be used as a criterion, Pfeiffer's bacillus was not demonstrated with enough frequency to support its claim as a causative agent. Its presence probably about coincided with its distribution in healthy persons at the time that the first wave appeared. During the second wave, however, the organism appears to have been found with great regularity.

In summary then, it appears that the Pfeiffer bacillus was absent or of low incidence in cases of the first wave and was almost uniformly present in cases of the second wave. How then could these differences in the bacterial flora during the two waves have influenced the severity of a disease caused by a type A influenza virus? Here I must again revert to consideration of swine influenza for a possible answer to this question.

As I have indicated earlier, infection of swine with the swine influenza virus alone results in an extremely mild respiratory disease of 2 or 3 days' duration from which the animals uniformly recover. However, swine infected with the swine influenza virus in combination with *H. influenzae suis* undergo a severe prostrating, febrile illness of 4 or 5 days' duration, frequently accompanied by pneumonia, from which death results in about 3 percent of all cases. In swine, then, the disease caused by the swine influenza virus alone resembles, in its mildness and other clinical characteristics, that seen in man during the first wave of the 1918 influenza, while the disease caused by a concomitant infection with the virus and *H. influenzae suis* resembles that seen during the second wave of the 1918 influenza. Furthermore, swine recovered from the mild ailment caused by infection with the virus alone are solidly immune to the more serious disease caused by infection with the virus plus *H. influenzae suis* (48).

It seems apparent, if the analogy between swine influenza and the 1918 influenza pandemic is an acceptable one, that the mild first wave of the 1918 pandemic can then be interpreted as one in which only a type A virus of the swine influenza prototype was involved. The second wave, on the other hand, was one in which the infection was a complex one, involving the same or an immunologically closely related type A virus and *H. influenzae*.

Applications to Present Outbreak

Let us now return to the current Asian influenza outbreak. If this outbreak is eventually to reach serious proportions, we appear at the moment to be in what in 1918 was the first wave. The cases ordinarily are not severe, and the mortality rate is relatively low. So far as I am aware, the Pfeiffer bacillus is not being isolated with any regularity from cases, and certainly it has not been reported to have been present in cases that have come to autopsy.

The current influenza may be considered on clinical grounds to be similar to a number of the outbreaks of interpandemic influenza that we have experienced since 1932 or to the first wave of the 1918 pandemic. We have no way of knowing at the moment whether it will be followed by a second wave of greater pathogenicity, as was the first wave in 1918. The fact that the human population is, in this outbreak, experiencing infection with a virus with which it has had no previous experience, to judge from the absence of specific antibodies, suggests that we may be ripe for a continuation of the present epidemic into a severe and killing second wave, but I do not think that anyone is, at the moment, in a position to predict accurately on this point.

Now, in the light of the speculations in which I have indulged, I should like to outline briefly my views as to how the present outbreak should be handled from a practical standpoint.

I believe it would be very foolish not to take full advantage of what means we have to protect ourselves. By this I mean that vaccination against the current epidemic strain seems to me to be strongly indicated. I think it is especially urgent that those who have apparently missed clinical infection during the early part of the present outbreak be immunized, since

they may be the very ones in whom occult virus has been preseeded. We have waited a long time to learn whether, when the next pandemic came along, we would be in a position to combat it, or only in a position to study pandemic influenza further. If we do not vaccinate widely and effectively and a second wave of severe influenza should appear, then undoubtedly we shall have copious opportunity again to study pandemic influenza. If we do vaccinate now, the most valuable information that can be derived will be whether or not we have finally gotten ourselves into a situation where we know that we can protect against outbreaks of pandemic influenza.

One frequently hears the view expressed that if another pandemic of severe and killing influenza occurs, the antibiotics can handle the situation satisfactorily by taking care of the lethal secondary bacterial invaders. Now this may be quite true for most of the commonly thought of complicating organisms. However, if *H. influenzae* should happen to be of importance, I doubt that we as yet have sufficient experience in treating infections of this organism in adults to be certain on this point. Although chloramphenicol, streptomycin, and the tetracycline antibiotics have been effective in *H. influenzae* infections in children, it seems to me that we are at the moment too deficient in accurate information to predict just how effective these antibiotics would be in treating adults, especially in the event that the hemophilus was acting concomitantly with influenza virus. In the light of such possible therapeutic uncertainties, I feel that primary reliance for protection against pandemic influenza should be placed on preventive rather than therapeutic procedures.

Milestone

All 70 sanitary inspectors of Costa Rica's Ministry of Public Health, studying in 3 groups, completed a 7-month course of classroom instruction and field demonstration introduced November 1954. Spanish language resumés of the various subjects, developed by Alberto Grego, sanitarian, helped make the training one of the more successful projects of the Cooperative Public Health Servicio.

The best three students from each group were sent to Puerto Rico for training in supervision. They will become a nucleus of supervisors to strengthen and improve the service of the section of sanitary inspection.

—CHARLES S. PINEO, *chief, health, welfare and housing field party, U. S. Operations Mission, Costa Rica.*

15th Anniversary

Serviço Especial de Saúde Pública completed 15 years of public health work in Brazil last July. Wherever SESP operates, festivities, speeches, and exhibits marked the anniversary of this cooperative health program.

Begun as emergency health work in the Amazon Valley supporting production of strategic materials during World War II, SESP has now spread over the entire country, operating in 461 localities. It is best known for its community health programs and water supply work.

About 1 million people a year receive some kind of direct service at SESP health units and at least another million are reached by home visitors, sanitary inspectors, and health educators. Eleven regional offices throughout the country direct the program of medical care, maternal and child health service, and environmental sanitation.

Five hundred water supply projects are already operating or under construction or being designed. A result of these projects, according to Professor

Herbert M. Bosch: "The development, largely through SESP efforts, of a full-time sanitary engineering specialty in Brazil over a period of 15 years is, I believe, without precedent in the world."

SESP is presently strengthening state and local government agencies to carry out health and sanitation work delegated to them by Brazil's constitution.

—E. ROSS JENNEY, M.D., *chief, Health and Sanitation Division, U. S. Operations Mission, Brazil.*

Earthquake in Ardestan

A woman sat on a mound of rubble that had once been her home, guarding her pots and pans and refusing to move. Then the Iranian nurse spoke to her gently and the gendarme led her away. A wall fell on a man while he slept in bed. A woman and her four children were found under the rubble in a home.

They were victims of an earthquake in Ardestan, Iran, last April. In 1 of the 7 villages hit, more than 250 houses were destroyed or damaged beyond occupancy. The disaster taxed the public health services staff but they worked tirelessly.

The injured were in a temporary hospital building. There nurses removed cotton placed over dirty wounds, cleaned them, and put on fresh dressings. A woman with bilateral leg fractures was taken by gendarme ambulance to Isfahan.

At the quake site, public health workers pitched a tent, set up priorities for treatment, and gave medical care. Patients swarmed in with ailments ranging from worms to skin diseases.

—GLEN W. McDONALD, M.D., M.P.H., *chief, Public Health Division, U. S. Operations Mission, Iran.*

Vanishing Yaws

Inspectors making their 11th house-to-house survey in the province of Esmeraldas, Ecuador, found yaws disappearing. Esmeraldas, a town of 20,000, had only 5 cases, 2 of them relapses, and Quindindé, with a population of 1,100 yielded only 6 cases, 5 of them relapses. Activities were intensified to find and treat all residual cases. The inaccessibility of isolated communities in northwest Ecuador makes this the most difficult phase of the anti-yaws campaign.

—JAMES D. CALDWELL, *chief, health, welfare and housing field party, U. S. Operations Mission, Ecuador.*

Opportunities in the United States Public Health Service, a 27-foot floor model, is one of the first Public Health Service exhibits under the expanded recruitment program. It won a Certificate of Merit from the Committee on Scientific Exhibits during

the 1955 meeting of the American Public Health Association. The box protruding from the center surface of the exhibit contains a motion picture projector for continuous showing of the recruitment filmograph "Service With Distinction."

Visual Aids for PHS Recruitment

At a time when the Nation is experiencing a shortage of qualified technical, professional, and scientific personnel, the Public Health Service, principally through its Division of Personnel, is developing and expanding a recruitment program for commissioned and civil service personnel to meet its own needs for specialists. Filmographs and exhibits produced by the Service are described here as examples of the types of materials being developed for the recruitment program.

FILMOGRAPHS

A black and white, 16-mm. filmograph, produced primarily to recruit professional and technical personnel for the Public Health Service Commissioned Corps, is being revised and converted to color and will be

ready by next spring. It bears the title "Service with Distinction" and was described in the July 1956 issue of *Public Health Reports*, shortly after it was originally produced. The black-and-white version has been shown to numerous health, medical, and nursing groups, as well as lay organizations, universities, and professional schools, throughout the country in the past 2 years. It is available, in black and white, also as a filmstrip, accompanied by recorded narration and music.

A 16-mm. filmograph in color, entitled "For the Nation's Health," was released recently by the Service. Although produced primarily for the orientation of Service employees, "For the Nation's Health" will be of interest also to health and medical personnel, students in professional schools, parents, teachers,

counselors, and community groups. It describes the origin, growth, organization, and work of the Service in nontechnical terms and provides the viewer with a clear understanding of the scope of its work. (See film announcement on page 164.)

Also new is the Service's nurse recruitment filmograph "Anyone For Nursing?" a 16 mm. production in color that is directed toward the recruitment of nurses in some of the Service's more interesting and challenging programs. Paced with sprightly music and humorous cartoons, it takes the viewer on a tour of the Public Health Service programs in which nurses are most active. These include the Public Health Service hospitals throughout the country, the clinical research programs of the National Institutes of Health, the Indian health pro-

The People We Serve . . . The Service We Give

There's a Spot for You in Nursing

gram in this country and Alaska, public health nursing activities, and the overseas health missions. Nurses are shown at work in the West, in the frontier environment of the sub-Arctic, and in foreign lands. (See film announcement in January 1958 issue, page 7.)

GENERAL EXHIBITS

Among the first recruitment exhibits produced by the Division of Personnel are a table-top model and a 27-foot prize-winning floor model entitled "Opportunities in the United States Public Health Service" (see illustration). The four-panel table-top model stands 32 inches high and is approximately 8 feet long when set up for display.

Recently completed by the Division is a series of exhibits each bearing the title "Service With Distinction," the keynote of the recruitment drive. Each exhibit in this series describes Federal-State-local health program relationships, opportunities for professional training in the Service, the growth and development of the Service since 1798, and the scope and variety of Service facilities and programs in this country and overseas (see illustration). Special mention is made of the Service's Commissioned Reserve program through which a national reserve of health and medical personnel is being organized, expanded, and trained for national emergencies.

The "Service With Distinction" series consists of two 17-foot floor exhibits, two 12-foot floor models, a 9-foot combination floor and table-top model, 40 table-top models, and 1,000 miniature counter-top displays. In addition, there is a refurbished film projection box, mounted on aluminum legs and bearing the theme title, for continuous showing of films at meetings. This unit also has a shelf for display of literature.

SPECIAL EXHIBITS

A number of programs in the Public Health Service are concerned with shortages of specific professional personnel. The following exhibits tailored to their needs have also been produced.

The Frontiers We Explore displays scenes illustrating opportunities for clinical nursing in the Public Health Service's National Institutes of Health, Bethesda, Md. (8 feet, floor model).

The People We Serve . . . The Service We Give, produced by the Division of Nursing Resources, depicts nursing opportunities throughout the Service (16 feet, floor model).

There's a Spot for You in Nursing, produced by the Division of Nursing Resources for the Committee on Careers of the National League for Nursing, illustrates nursing opportunities for nursing aides, practical nurses, professional nurses, and teachers, supervisors, and administrators (8 feet, floor model; 5 feet, table-top model).

Opportunities for Nurses, produced by the Division of Personnel, is designed to recruit nurses to meet needs throughout the Service (four panels of aluminum, each 30 inches high by 18 inches wide, portable table-top model; three models in use).

Indian Health Service Nursing . . . The Challenge We Meet, produced by the Division of Indian Health, shows how nurses in the Indian health program accept the challenge of providing hospital and public health services for 370,000 Indians and Alaskan natives (8 feet, floor model).

Sanitation Services for Indians . . . The Challenge We Meet, a new exhibit created by changing the headboard and photographs in the above display, depicts the Indian health activities of sanitary engineers (8 feet, floor model).

Health Careers Among the American Indians, designed by the Division of Indian Health, aims to interest professional personnel in the full range of therapeutic and preventive services provided by the Indian health program (9 feet, folding floor model).

A New Approach to Indian Health, created by the Division of Indian Health, describes opportunities for professional personnel to work with other disciplines in the Indian health program (12 feet, floor model).

Opportunities for Nurses

Indian Health Service Nursing . . . The Challenge We Meet

Health Careers Among the American Indians

The Research Patient depicts activities of personnel staffing the supporting professional services in the Clinical Center, National Institutes of Health, Bethesda, Md. Photographs show how the research dietitian, research nurse, research social worker, and research therapist work together for the benefit of the research patient and, ultimately, of medical science (18 feet, floor model).

A New Approach to Indian Health

Opportunities for Engineers and Scientists was produced by the Division of Personnel, with the assistance of the Division of Sanitary Engineering Services, for recruitment of sanitary engineers, nuclear physicists, public health engineers, chemists and biologists, civil and other engineers, and sanitarians (four panels of pressed wood, each 2 feet high by 3 feet wide, portable table-top model; 20 models in use).

These Public Health Service recruitment films and exhibits have been in wide circulation at professional meetings during the past winter. Inquiries about availability may be directed to the Surgeon General, U. S. Public Health Service (P), Washington 25, D. C.

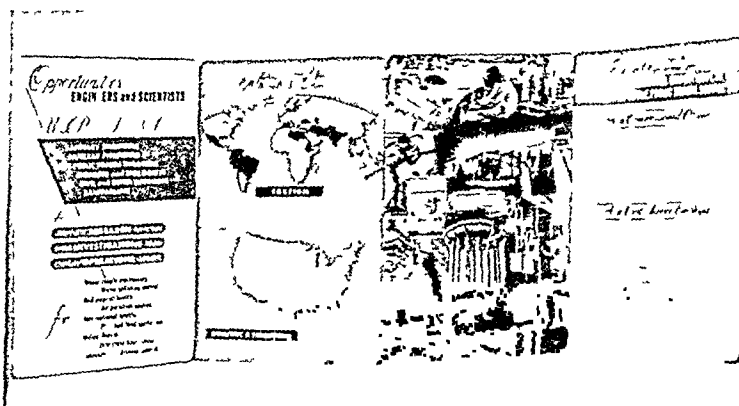

NATIONAL HEALTH COUNCIL FILM

The need for recruiting manpower for health careers has also been recognized by many voluntary agencies. An example is the 15-minute documentary film entitled "Health Careers," produced by the National Health Council as part of its Health Careers Horizons project. Like the Council's well-known publication, Health Careers Guidebook, this film is designed to interest young people in entering the health professions. It is a black and white 16-mm. film with sound track.

The film was developed with the guidance of 20 consultants representing secondary education and school counseling services for presentation to teen-agers, parents, counselors, teachers, and community groups. Inquiries about the film should be directed to Health Careers, National Health Council, 1790 Broadway, New York 19, N. Y.

Opportunities for Engineers and Scientists

Health Insurance Coverage for Mental Illness

LOUIS S. REED, Ph.D.

TODAY in the United States approximately 116 million people have some health insurance coverage for hospital care: 101 million, for surgical service; 65 million, for medical service in the hospital; and 9 million, for physician service in the office, clinic, and home. Major health insurance carriers are the Blue Cross and Blue Shield plans, insurance companies through group and individual policies, and independent plans. The last type includes company and union self-insured plans, community-sponsored plans, and prepayment programs offered by private medical groups. Table 1 shows the number of persons covered for the various services by each type of plan.

Prepayment plans generally provide less extensive coverage for mental illness than for other types of illness. In part at least, this is due to the long duration of mental illness, to the fact that mental illness has traditionally been considered as separate and apart from other illness, and to the fact that much of the hospitalization for mental illness is provided

in government hospitals at little or no cost to the patient or his family.

The lesser coverage for mental illness creates problems for the subscribing public, for hospitals, and for the medical profession in general and psychiatrists in particular. To elucidate the present situation as regards coverage, I shall describe in turn the practices of each type of plan.

Blue Cross Plans

Most of the 80 Blue Cross plans in the United States offer two or more, and some a whole host of, subscriber contracts with varying provisions regarding duration of benefits, type of room or amount of room allowances, and the like. Some provide better coverage of mental and nervous cases (the terminology generally used by the plans) under one contract than under another. I shall deal only with the most extensive contracts of each plan.

The plans provide far less extensive coverage of mental illness than of other types of illness in general hospitals, and they provide far less extensive coverage of mental illness in mental than in general hospitals (table 2). The majority of the plans provide a maximum of between 60 and 120 days of care, generally per admission, for general illness. By contrast, 18 of the 80 plans provide no coverage whatever of mental and nervous cases in general hospitals, 3 provide coverage only until diagnosis as a mental case, and 1 covers for shock therapy or surgery only. Of the remaining plans, 8 provide 7 to 20 days of coverage, and 27, or about a third, between 21 and 30 days. Only 16

Dr. Reed is associate professor of medical economics, Sloan Institute of Hospital Administration, Cornell University. Long interested in the economics of medical care and prepayment plans, he made a nationwide survey of Blue Cross and related medical service plans in 1944-47. A paper on employee health benefit plans by Dr. Reed was published in the December 1957 issue of Public Health Reports. The present paper is based on one he delivered at the annual meeting of the American Psychiatric Association on May 14, 1957, in Chicago, Ill.

Table 1. Health insurance coverage in the United States, by type of coverage, according to type of carrier, Dec. 31, 1956

[Thousands of persons covered]

Net total	115, 949	101, 325	64, 891	8, 700	7, 459	1, 413

¹ A fair number of the Blue Cross-Blue Shield plans have "dread disease" or "prolonged illness" supplementary contracts or riders which offer a coverage somewhat analogous to the major medical expense policies of insurance companies. Also, a few plans have issued major medical contracts. The number of persons covered under these supplementary Blue Cross-Blue Shield contracts is not known; it is probably in excess of 4 million.

Source: Data in all columns except "Medical service in office and home" are from the Health Insurance Council's The Extent of Voluntary Health Insurance Coverage in the United States as of December 31, 1956. Data in that column are my own rough estimates. The presentation of the data differs somewhat from that in the council's publication.

of the plans provide as many as 60 days of coverage in general hospitals. A few of the plans further limit coverage for mental illness by specifying that the prescribed number of days for mental care shall be the total provided during the lifetime of the member.

So far as I can calculate, approximately 30 percent of the plans provide the same coverage for mental cases in general hospitals as they provide for general illness; the remainder provide less or no coverage.

The coverage provided in mental hospitals is still less extensive. Almost half of the plans provide no coverage whatever; 3 cover only until diagnosis as a mental case; 1 covers for shock therapy or surgery only; 5 provide less than 21 days; 23, between 21 and 30 days; and only 10, more than 30 days. In a number of the plans these days are the maximum provided for life. Two plans exclude all care in government hospitals, and several exclude care available without charge in government hospitals. These provisions indicate that there is some question as to whether the State mental hospitals of the area charge for their services or not.

Several plans provide extensive coverage for mental cases. One provides up to 120 days per admission in either general or mental hospitals. Three of the plans offer special riders to their regular policies which provide an extra coverage of mental cases. Two of these, one at a cost of 12 cents and another at 15 cents a month for a family, provide up to 30 days for mental cases in either general or mental hospitals. The third, at a cost of 10 cents a month for a family, will extend the coverage for mental cases from the 30 days available under its ordinary certificate to 120 days in either general or mental hospitals.

The provisions of the plans regarding alcoholism, drug addiction, and self-inflicted injuries (attempts at suicide) are pertinent here. About two-thirds of the plans provide some coverage for alcoholism and for drug addiction, and almost all cover self-inflicted injuries (table 3).

Blue Cross coverage of mental illness has distinctly improved over the past decade. Ten years ago half of the plans excluded all coverage even in general hospitals, and only 5 out of

81 plans provided benefits in general hospitals for as long as 31 days.

Blue Shield Plans

Of the 64 Blue Shield plans, 4 provide only surgical service, 51 cover surgical and in-hospital medical service, and 9, under at least one of their contracts, also cover physicians' services in the office and home.

Thirty-three, or a few more than half, of the plans cover mental and nervous conditions on the same basis as all other conditions; 21 totally exclude these conditions; and the remaining 10 provide limited coverage (table 4). Mostly these last limit care to less than 30 days or to that provided in general hospitals.

Special interest attaches to the nine plans which offer comprehensive coverage of physicians' services, that is, care in the office, home, and hospital. Of these, 4 provide the same coverage for mental and nervous conditions as for

Table 2. Blue Cross coverage for general conditions and for mental conditions in general and mental hospitals, January 1957: number of plans providing specified days under most extensive contract

other conditions; 1 totally excludes these conditions; 1 covers only shock treatments or surgery; 1 covers only diagnosis in the office; 1 excepts psychiatric treatment; and 1 provides coverage for only 30 days.

About two-thirds of all Blue Shield plans provide some coverage of alcoholism and drug addiction, and the great majority cover self-inflicted injuries (table 4).

Insurance Companies

I shall deal first with group policies and then with individual policies.

Group insurance plans sold by insurance companies generally provide hospitalization coverage for 31 days or 70 days, occasionally for 120 days, and rarely for 180 days. With rare exceptions, these policies provide the same coverage for mental illness, alcoholism, drug addiction, and self-inflicted injuries as for all other

types of cases, and without distinction as to type of hospital.

Group surgical and in-hospital medical policies of insurance companies likewise usually cover these cases on the same terms as all other types of cases.

Most companies also sell group policies providing coverage of medical calls in the office and home, usually on a 2- or 3-visit deductible basis. In general these plans cover mental or nervous conditions; however, most are written with the condition that, for the employee, benefits will be paid only if he is disabled.

Within the past 6 years there has been a rapid growth of a type of insurance known as major medical expense insurance, written mainly on a group basis. This insurance supplements the basic hospital, surgical, and medical coverages and usually pays 75 percent of all medical care expense beyond the benefits under the basic coverages and a deductible amount paid by the insured. Within the past 3 years there has been a rapid growth of another type of insurance, called comprehensive medical expense insurance. These policies combine the basic and major medical coverages into a single package. They pay 75 to 85 percent of virtually all medical costs over specified initial deductible amounts and up to high maximum limits.

The practices under these policies in covering mental cases vary. Some policies cover mental illness on the same terms as all other illness. Other plans do this with the proviso that if the employee is not disabled or the dependent hospitalized the rate of reimbursement of expense for psychiatric treatment or consultations will be 50 percent instead of the usual 75 to 85 percent. Still other plans provide reimbursement in mental illness only for patients who are totally disabled or confined in a hospital.

Most of the major medical or comprehensive policies are rather new, and thus experience has been limited. Quite possibly the companies have not yet come fully to grips with the problems of providing care economically and at reasonable costs. In a letter to the author, one large company writes:

"The broad coverage [of mental illness now provided] may be of short duration. In one particular group policy . . . the claims for

Table 4. Blue Shield coverage of mental and nervous conditions, alcoholism, drug addiction, and self-inflicted injuries, March 1957: number of plans with indicated provision

Provision	Nervous and mental conditions	Alcoholism	Drug addiction	Self-inflicted injuries
Covers ¹ -----	33	35	38	51
Excludes-----	21	25	22	16
Limited coverage-----	10	4	4	1
Total-----	64	64	64	64

¹ To the same extent as other types of cases.

² 5 cover for a limited period, from 10 to 30 days; 2 cover only in general hospitals: 1 covers for shock therapy only; 1 covers for diagnosis only, and 1 cover except for psychiatric treatment.

³ 2 cover only in general hospitals; 1 covers for 30 days only; and 1 covers except for psychiatric treatment.

SOURCE: Compiled from data in Blue Shield Manual as revised to March 1957.

treatment of mental or nervous conditions amounted to well over one-third of the total claims, exclusive of maternity claims. The psychiatric charges at the beginning . . . were in the \$20 and \$25 bracket and the frequency was averaging between 1 and 2 treatments a week. Gradually the charges increased to \$36 a visit and the frequency to 6 times per week with no disability . . . involved.

"Obviously if we are to continue the broad coverage contemplated we must have some pattern which will show an insurable risk—a risk that we can measure and for which we can establish a premium."

Health insurance policies sold to individuals vary perhaps even more widely than group policies, and some companies issue a multitude of different policies with different provisions. Data on number of persons covered under the different provisions are not available. My impression is that the majority of policies exclude mental illness.

Independent Plans

Some of the independent plans are doing interesting experimentation in the coverage of mental illness.

The medical program of the United Mine Workers Welfare and Retirement Fund will

pay for care of patients with mental illness in general hospitals and will provide virtually unlimited care by psychiatrists in the office or outpatient department, to the extent such services are deemed essential. It pays for care in mental hospitals only when the prospect is that the patient will respond to care in a relatively short period, say 1 or 2 months.

The Health Insurance Plan of Greater New York, which provides service through medical groups, excludes alcoholism, drug addiction, and "coverage for psychiatric disorders after diagnosis, for which care is customarily provided by a psychiatrist." Each medical group is required to have a board-certified psychiatrist. The physicians in the group refer patients to him for diagnosis, and in establishing a diagnosis there is usually some form of treatment. However, the groups do not provide shock therapy or analysis. Visits to psychiatrists-neurologists amount to $\frac{1}{2}$ of 1 percent of the total number of services provided by all group physicians to members of the plan.

The Kaiser Foundation Health Plan, which provides services through its own medical groups and hospitals, excludes care for mental illnesses or disorders, attempts at suicide, and alcoholism. However, two of the larger medical centers now have psychiatric clinics. These provide testing and therapy at low fees, usually \$5 an hour. The personnel at one clinic includes 2 full-time and 1 part-time psychiatrist, 4 psychologists, and 2 psychiatric social workers. The extra fees charged subscribers do not pay the full expenses of the clinic, which is subsidized by the program as a whole. The program is reported to be very useful in relieving other services of chronic patients whose illnesses are more psychological than somatic.

Group Health Association in Washington, D. C., excludes psychiatric treatment. However, the staff includes two part-time psychologists who provide counseling service to subscribers at a charge of \$7 an hour.

The St. Louis Labor Health Institute provides psychiatric service. The staff includes 3 psychiatrists and 1 clinical psychologist, whose hours of service represent about 3 percent of the total of all physician hours.

Most of the large union health centers have part-time psychiatrists on their staffs. Psy-

chiatric visits tend to be about 1 or 2 percent of all visits.

These examples will suffice to indicate practices of independent plans. It is perhaps easier for plans which operate on group-practice principles to experiment with psychiatric coverage than it is for plans providing benefits through free-choice, fee-for-service arrangements.

Notes on Costs and Problems

A few figures may give some idea of the general magnitude of potential costs for coverage of hospitalization for patients with mental illness:

- At present about 2 percent of all patient-days in short-term general hospitals are for patients in the psychiatric units of these hospitals. This fact indicates that on the basis of prevailing practices full coverage of psychiatric cases in general hospitals should not increase a health insurance plan's costs by more than 2 percent.

- If prepayment plans undertook responsibility for the first 60 days of all admissions to all mental hospitals, including State institutions, and provided an average of 45 days per admission, they would assume liability for days of care amounting to an additional 10 percent of all days for general care. Since the cost per day in mental hospitals is, of course, lower than for general hospitals, this would represent less than a 10 percent increase in costs.

- One Blue Cross plan which covers mental cases for 120 days in general hospitals and for 30 days in other hospitals reports that its payments for mental, psychoneurotic, and personality disorder cases amount to 3.2 percent of its total inpatient payments. An insurance company estimates that under its basic hospitalization plans 3 to 5 percent of its hospital expense is for psychoneurotic disorders.

Among the problems in providing coverage for mental illness are the costs, in a setting where all types of plans are finding their costs expanding; the indeterminateness of these costs particularly when care over a long period in a hospital or physician's office is required; the question of how mental hospitals in this country should be financed and of demarcation of

the respective roles of patients, private insurance, and government in financing mental hospital care. All real coverage of psychiatric care in the office must await the development of prepayment for physicians' services generally in the office and home, a field in which experimentation and pioneering are the order of the day.

A quotation from a letter I received from the director of one independent prepayment

plan may well sum up the present position of prepayment plans and insurance carriers on coverage for psychiatric care:

"It seems to me that the most important fact is that no one has any idea as to what the utilization of complete psychiatric services would be if they were available on an insured basis. It is our hope, therefore, to extend coverage in this field bit by bit so as to learn as we go along, while avoiding too great a risk."

National Health Survey Advisory Committee

To enhance the usefulness of the U. S. National Health Survey of the Public Health Service, an advisory committee has been set up to include representatives of the health professions, insurance firms, labor, and other users of health statistics.

The new committee will review the plans and progress of the survey and help formulate principles and methods of cooperation with interested public and private organizations.

Leroy E. Burney, Surgeon General of the Public Health Service, is chairman of the committee, and George St.J. Perrott, chief of the Service's Division of Public Health Methods, serves as executive secretary.

The committee held its first meeting November 22, 1957.

Members of the committee are: Dr. Karl Bambach, vice president, American Drug Manufacturers Association, Washington, D. C.; Dr. Leona Baumgartner, commissioner of health, New York City; Pearl Bierman, medical care consultant, American Public Welfare Association, Chicago, Ill.; Dr. Paul E. Boyle, dean, School of Dentistry, Western Reserve University, Cleveland, Ohio; James Brindle, director, Social Security Department, United Auto Workers, Detroit; Arthur M. Browning, vice president, New York Life Insurance Co., New York City; Dr. W. D. Bryant, executive director, Community Studies, Inc., Kansas City, Mo.

Other members are: Dr. Bernard Bucove, State director of health, Olympia, Wash.; Dr.

Robin C. Buerki, executive director, Henry Ford Hospital, Detroit; George Bugbee, president, Health Information Foundation, New York City; Dr. Antonio Ciocco, head, Department of Biostatistics, Graduate School of Public Health, University of Pittsburgh; James F. Coleman, president, United Medical Service, Inc., New York City; Dr. J. S. Denslow, professor and director of research affairs, Kirksville College of Osteopathy and Surgery, Kirksville, Mo.; Dr. Robert P. Fischelis, secretary, American Pharmaceutical Association, Washington, D. C.

Also on the committee are: Dr. Norvin C. Kiefer, chief medical director, The Equitable Life Assurance Society of the United States, New York City; Dr. Allister M. Macmillan, Department of Sociology and Anthropology, Cornell University, Ithaca, N. Y.; Dr. Ross A. McFarland, Department of Industrial Hygiene, School of Public Health, Harvard University, Boston; Dr. H. B. Mulholland, Department of Internal Medicine, School of Medicine, University of Virginia, Charlottesville; Dr. Peter M. Murray, board of trustees, State University of New York, Albany.

Completing the list of members are: Marian G. Randall, R.N., executive director, Visiting Nurse Service of New York; Dr. Vergil D. Reed, vice president, J. Walter Thompson Co., New York City; Dr. James H. Sterner, medical director, Eastman Kodak Company, Rochester, N. Y.; James E. Stuart, executive director, Hospital Care Corporation, Cincinnati, Ohio; and Dr. Ray E. Trussell, executive officer, School of Public Health and Administrative Medicine, Columbia University, New York City.

Cost Analysis for Collegiate Programs In Nursing

Part I. Analysis of expenditures
Part II. Current income and other resources

National League for Nursing and PHS Publication. By Leslie W. Knott, Ellucynne M. Vreeland, and Marjorie Gooch. Part I, 1956, 166 pages; \$3.50. Part II, 1957, 46 pages; \$2.00.

Although these manuals are focused on analyzing costs of nursing education, the techniques and methods described should prove useful for other types of education programs.

Part I contains a general discussion of underlying principles, defines terms, and describes the methods used. Part II, in addition to discussing the usual sources of education income, includes suggested methods for evaluating student service.

Schedule forms for organizing and analyzing cost information are presented with illustrative data based on a fictitious university carried through the analysis step by step.

Copies can be obtained from the National League for Nursing, 2 Park Avenue, New York 16, New York.

Reported Tuberculosis Data, Calendar Year 1955

PHS Publication No. 560. 1957. By Stanley Glaser and Paul L. Roney. 29 pages. 25 cents.

This fourth annual summary presents data supplied to the Public Health Service on the Annual Tuberculosis Report by all the States, the District of Columbia, Alaska, Hawaii, and Puerto Rico.

The data cover newly reported tuberculosis cases for the United

States and each State by source of morbidity report, activity status, form and extent of the disease, race, sex, and age, as well as X-ray case-finding activities, mortality, and public health nursing visits.

An analysis of each table summarizes data for the years 1952 through 1955 and points out pertinent characteristics inherent in the data.

Biological Products

PHS Publication No. 50. Revised April 15, 1957. 52 pages.

Superseding Public Health Service Publication No. 50, revised April 15, 1955, this edition lists the establishments holding licenses for the preparation and sale of viruses, serums, toxins and analogous products, and the trivalent organic arsenic compounds.

Comparative Mortality Among Metropolitan Areas of the United States, 1949-51

102 causes of death

PHS Publication No. 562. 1957. By Nicholas E. Manos. 143 pages. \$3.25.

This graphic and tabular presentation of 1949-51 mortality, from 102 causes, in the United States includes ratios of observed to expected mortality for 163 metropolitan areas; mortality rates and ratios by degree of urbanization; and background material necessary to the interpretation of these data. It was prepared under the direction of the Air Pollution Medical Program, Public Health Service.

Mortality ratios are emphasized as a tool for comparative analysis, and mortality data are presented in greater geographic detail than has heretofore been available.

The 102 causes of death are grouped into 10 categories, including respiratory system diseases, circulatory system diseases, malignant neoplasms, and a group of miscellaneous diseases and conditions. Mortality comparisons from city to city, by cause, as well as comparisons between the central city and outlying areas of the 163 metropolitan areas, are shown.

While no analysis accompanies the statistics, the graphic form of presentation points up variations which suggest possible areas of research on the effects of environmental factors on mortality.

Meeting Community Sewage Treatment Needs Under the Construction Grants Program

PHS Publication No. 558. 1957. Folder.

The Federal grant program for construction of sewage treatment works, authorized under the Federal Water Pollution Control Act, Public Law 660, 84th Cong., is briefly described. Eligibility requirements and application procedures are outlined, and State water pollution control agencies cooperating with the Public Health Service in administering the program are listed.

Handbook of Selected Biological References on Water Pollution Control, Sewage Treatment, Water Treatment

Public Health Bibliography Series No. 8. PHS Publication No. 214. Revised 1957. By William Marcus Ingram. 95 pages; illustrated. 45 cents.

This revised handbook lists by subject numerous biological publications relating to various aspects of water pollution, waste treatment, and water supply that have appeared in recent technical literature. The references were selected on the basis

of their availability and potential usefulness to those not trained primarily in biology. The intent of the handbook is to provide information fundamental to a good understanding of biological problems that could arise in the course of water pollution control and related work.

A list of references on organism identification is included. Basic readings on ecology and water treatment are suggested in the introduction.

Facts About the Federal Water Pollution Control Act of 1956

PHS Publication No. 555. 1957. 16 pages. 15 cents.

Intended for community leaders, State and municipal officials, and others interested in control of water pollution, this booklet outlines briefly the provisions of the Federal Water Pollution Control Act of 1956 (Public Law 660, 84th Cong.) and the Public Health Service program authorized by the new law. Activities under this program include comprehensive program development, interstate cooperation, research and technical assistance, collection of basic data, State and interstate program grants, construction grants, and enforcement measures against interstate pollution.

Background information on earlier Federal legislation for pollution control is given, and the role which control of pollution plays in augmenting and conserving water resources to meet increasing demands is described.

How To Study Supervisor Activities in a Hospital Nursing Service

PHS Publication No. 496. 1957. By Elinor D. Stanford and others. 47 pages. 40 cents.

Third in a series developed by the Division of Nursing Resources, Public Health Service, for use by hospitals and others desiring to study

nursing personnel activities, this manual provides the supervisor with a method for examining her actual activities in relation to the functions which she believes appropriate to her job. The steps in the study and the method of observation employed are described in detail.

Instructions for training observers and for tabulating material are included.

Directory of Full-Time Local Health Units, 1957

PHS Publication No. 118. Revised 1957. 70 pages. 30 cents.

This listing of full-time health units serving local areas, together with the name of the health officer of each unit or other designated administrative head, was revised July 1957. The local units are listed by State, giving in each instance the health area jurisdiction, post office address, and the health officer's name and official title.

Facts About Indian Health

PHS. Publication No. 479. Revised June 1957. 8 pages.

With up-to-date statistics and facts, this revised edition describes briefly the Indian health problem and the program of the Division of Indian Health, Public Health Service.

Socioeconomic Characteristics of Persons Who Married Between January 1947 and June 1954: United States

Vital Statistics—Special Reports. Selected Studies. Vol. 45, No. 12, Sept. 9, 1957. By Hugh Carter, Sarah Lewitt, and William F. Pratt. Pages 271-353; tables and charts. 45 cents.

Based on a sample survey of persons who married between January 1947 and mid-June 1954, data are

given on residence at time of marriage as related to place of marriage, number of times previously widowed or previously divorced, number of times married, age at marriage, years of school completed, labor-force status of wife, and major industry group of husband.

There are cross tabulations of characteristics of the husband as related to those of the wife, as well as separate tabulations for husbands and wives. An analytical text, text tables, and charts precede 30 detailed tables of basic data.

The data were obtained through a special supplementary survey carried out by the Bureau of the Census in its current population survey. Tables of sampling errors are included.

Facts on Mental Health and Mental Illness

PHS Publication No. 543. 1957. 11 pages. 10 cents.

Known facts about mental illness are summarized and the need to know more is pointed out in this booklet. It shows the scope of the problem and cites new knowledge gleaned through recent research as well as progress made in the care, treatment, and rehabilitation of the mentally ill, and in the training of specialists in the mental health field. What is needed to solve this major health problem is outlined.

This section carries announcements of new publications prepared by the Public Health Service and of selected publications prepared by other Federal agencies.

Unless otherwise indicated, publications for which prices are quoted are for sale by the Superintendent of Documents, U. S. Government Printing Office, Washington 25, D. C. Orders should be accompanied by cash, check, or money order and should fully identify the publication. Public Health Service publications which do not carry price quotations, as well as single sample copies of those for which prices are shown, can be obtained without charge from the Public Inquiries Branch, Office of Information, Public Health Service, Washington 25, D. C.

The Public Health Service does not supply publications other than its own.

New Viruses Observed in Children With Respiratory Diseases

ROBERT M. CHANOCK, M.D., ROBERT H. PARROTT, M.D., JOSEPH A. BELL, M.D.,
WALLACE P. ROWE, M.D., and ROBERT J. HUEBNER, M.D.

EVENTUAL control of the common respiratory diseases depends on the determination of their etiology. Despite recent notable advances in delineating the viral etiology of such illnesses—at least 70 newly recognized viral agents have been described since 1948—the causes of most remain to be found. The preliminary report outlined here presents data on two new respiratory viruses which have been found in children with respiratory illnesses and which, while biologically related to influenza and mumps, are also quite distinct.

Previously unrecognized myxoviruses classified in two serologic groups were isolated from children with respiratory illnesses during October and November 1957 (1). These two new groups of agents, provisionally called hemadsorption (HA) viruses types 1 and 2, were isolated in monkey kidney cultures with the use of the hemadsorption technique recently introduced by Vogel and Shelokov (2, 3). Preliminary clinical and epidemiological observations indicated that these agents might be responsible for a proportion of the common acute respiratory illnesses in children which remain largely unexplained despite recent advances exemplified by the discovery of adenoviruses (4, 5) and other new agents (6-9).

The type 1 HA virus was isolated from 35

children, 8 of whom were studied in Washington, D. C., hospitals and 27 of whom were involved in an outbreak of febrile respiratory illness in a nursery group of a District of Columbia welfare institution (Junior Village). When throat swabs were collected on one day from all infants in the affected nursery and tested for HA viruses, epidemiological analysis indicated that there was a significant association of type 1 HA virus isolations with febrile illnesses (chi-square test indicated $P=0.03$), thus strongly suggesting but not proving an etiological relationship. The illnesses were characterized by fever of 2 to 3 days' duration and cough. Nearly half of the cases had moist medium to fine rales; several had coarse breath sounds and rhonchi.

Type 2 HA virus was isolated from three infants with acute laryngotracheobronchitis (croup), and more experience will be required with this agent before its etiological importance in disease can be determined.

Acute and convalescent serum specimens from patients yielding either type 1 or type 2 virus showed substantial antibody rises in complement fixation and hemagglutination inhibition tests. Specimens from 82 hospitalized patients without respiratory illnesses did not yield the two viruses.

The contribution of the HA viruses to the total respiratory disease picture cannot be assessed at this time. However, serologic data suggest that the contribution of these agents to childhood respiratory illnesses may be substantial. Preliminary surveys for antibodies against HA viruses in the serums of 55 adults,

Dr. Chanock, Dr. Bell, Dr. Rowe, and Dr. Huebner are all with the Laboratory of Infectious Diseases, National Institute of Allergy and Infectious Diseases, Public Health Service. Dr. Parrott is physician-in-chief of Children's Hospital, Washington, D. C., with which Dr. Chanock is also associated.

nearly all young males, showed that all had neutralizing antibodies to type 1 virus, and 39 had neutralizing antibodies to type 2.

The following properties indicated that the HA viruses are members of the myxovirus family. Both types 1 and 2 HA viruses agglutinated guinea pig and chicken red cells: They propagated in the amniotic cavity of the embryonated hen's egg, they possessed erythrocyte

receptors sensitive to RDE (receptor destroying enzyme of *Vibrio cholerae* filtrate), and they were sensitive to ether.

Studies of the serologic relationships of HA viruses to other myxoviruses, as determined by the use of specific animal serum, are reported elsewhere (1). The table shows distinct immunological differences from influenza A, B, and C, mumps, and croup associated (CA)

Relationship of types 1 and 2 hemadsorption (HA) virus to certain myxoviruses, as shown by representative complement fixation tests with human serums

viruses, as shown through use of paired acute and convalescent serums from patients with HA and influenza virus infections.

In representative complement fixation tests, persons infected with both type 1 and type 2 showed no rises to influenza A, B, or C when tested against the group-specific CF antigens of these agents. Type 1 HA virus was shown to be different from Sendai, mumps, and CA viruses by these same serums. Type 2 HA virus was not related to mumps or CA virus, but showed a relationship to Sendai virus, which has recently been proposed as the prototype influenza D virus (10). Children who were infected with type 2 HA virus, and who developed complement fixing antibody for the homologous virus, also developed antibody for Sendai viral antigen but not for the Sendai chorio-allantoic membrane extract (soluble) antigen. Guinea pigs immunized with Sendai virus also developed CF antibody to type 2 HA virus, but in the hemagglutination inhibition and neutralization tests these agents were shown to be distinct (1).

International Classification of Diseases Revised

The seventh revision of the Manual of the International Statistical Classification of Diseases, Injuries, and Causes of Death, effective January 1958, to be used by the United States and other members of the World Health Organization for the next 10 years, is now available in two volumes, at \$3.50 for the set. The first volume contains the classification: the second, the alphabetical index. The Public Health Conference on Records and Statistics is again consolidating orders in the United States. Orders and checks payable to that organization may be addressed c/o Department of Health, Education, and Welfare, National Office of Vital Statistics, Washington 25, D. C.

New Members of the PHR Board of Editors

Dr. Chope

Mr. Hunter

Dr. Kidd

Dr. Langmuir

Dr. Sowder

Five new members will attend the April meeting of the Board of Editors of Public Health Reports. Retired from the Board are Harold M. Erickson, Lloyd Florio, Victor H. Haas, and Seward E. Miller.

Harold D. Chope, M.D., Dr.P.H., has been director of the San Mateo County (Calif.) Department of Public Health and Welfare since 1948. After taking his doctorate in public health from Harvard University (1940) where he had also been a Rockefeller Foundation fellow during work on his master's degree, he was, from 1940 to 1948, successively, associate in public health administration at Harvard; Rockefeller Foundation staff member in São Paulo, Brazil; and assistant district health officer, San Joaquin Local Health District, Stockton, Calif. Prior to 1940 he served as chief of the bureau of epidemiology, St. Louis City Health Department, assistant director of the California State Health Department, and health officer, Newton, Mass. From 1936 to 1941 he lectured at the Simmons School of Public Health Nursing and directed a field training unit at Harvard from 1935 to 1940. He was clinical professor of preventive medicine at Stanford University in 1955, and, from 1947 to the present, has been lecturer at the University of California School of Public Health.

J. Stewart Hunter, M.A., assistant to the Surgeon General of the Public Health Service since 1950, serves as staff adviser on public information and supervises the information and publications programs of the Service. From March 1953 until October 1955, at the request of the Department, he served as acting director of publications and reports for the Secretary of Health, Education, and Welfare. He came to the Service in June 1949 from a position as associate director of the public relations department of the Chicago office of J. Walter Thompson Co. After serving on the information staff of the Office of Price Administration during the early part of 1942, he saw active duty as lieutenant commander in the U. S. Naval Reserve from October 1942 to January 1946, the majority of the time as an officer on an aircraft carrier in the Pacific. Subsequently, he lectured in English at Northwestern University. He is a graduate

of the University of Pittsburgh, where he taught from 1930 to 1942, except during 1937-38, when he served as associate and managing editor of the *Pittsburgh Bulletin Index*.

Charles V. Kidd, Ph.D., has been chief of the Office of Research Planning of the National Institutes of Health, Public Health Service, since 1949. He is also executive secretary of the consultants on medical research and education to the Secretary of Health, Education, and Welfare. In 1947 he was executive secretary of the President's Scientific Research Board, and later was a staff member of the President's Council of Economic Advisers. He received a Rockefeller public service award in 1955. He took an A.B. from Princeton in 1935, a diploma in history from Munich in 1936, and a Harvard doctorate in 1937.

Alexander D. Langmuir, M.D., M.P.H., has been chief of the Epidemiology Branch, Communicable Disease Center, Public Health Service, since 1949. From August 1942 to July 1946, he was the epidemiologist of the Commission on Acute Respiratory Diseases of the Army Epidemiological Board, Fort Bragg, N. C. He served in the New York State Department of Health from February 1937 to August 1942 in various capacities, including that of deputy commissioner of health of Westchester County. Before coming to the Communicable Disease Center, he was associate professor of epidemiology at Johns Hopkins School of Hygiene and Public Health for 3 years. In 1955 he served as a member of the WHO Committee on Poliomyelitis Vaccine. Since 1947 he has been consultant on biological warfare to the Secretary of Defense.

Wilson T. Sowder, M.D., M.P.H., Florida State health officer for the last 13 years, entered the Public Health Service as a commissioned officer in 1931. He served in hospitals, quarantine stations, and the Coast Guard, and in venereal disease control work in Tennessee and Florida. He was also a consultant on communicable diseases in the War Shipping Administration and consultant in the Service's regional office in Dallas, Tex., until his resignation in 1956 from the Regular Corps to remain in Florida. He took his medical degree in 1932 from the University of Virginia, and his master's degree in public health from the Johns Hopkins University in 1939.

Radiation as a Public Health Problem

DAVID E. PRICE, M.D.

TO BE CLASSIFIED as a public health problem, a hazard must bear an important relationship to human health or disease. It must, furthermore, affect a significant part of the population, and it must be amenable to remedial action which is within the power of society to undertake.

Unquestionably, ionizing radiation meets the first two of these criteria. It has a relationship to human health and affects a significant part of the population. However, the design of social action deserves thoughtful consideration.

Past experience in public health has taught us that a problem usually becomes rather serious before people band together to deal with it. Only when a considerable amount of disease could be traced to polluted water did we begin to develop sewage treatment and other antipollution measures. Only when motor accidents had taken an alarming toll did citizens insist on better roads, safety devices, and various accident prevention programs. Traditionally, and in the main this is probably one of mankind's happier traits, we do not go looking for trouble. Not until the trouble looms so large it can no longer be ignored do we find the incentive to band together and pool resources—neighborhood, city, State, or Nation—to do something about it.

In dealing with the health hazards of ionizing radiation, unfortunately, this traditional approach cannot promise success. The effects of ionizing radiation are cumulative and irreversible. They are subtle and may become ap-

parent only after long delay. If we wait until there are obvious signs of radiation damage it will be too late to help the affected population or to decontaminate the polluted environment successfully. In this situation, prevention is not merely desirable, it is imperative.

Finding the proper incentive to stimulate preventive action, however, is not easy. In my opinion, to use fear as the incentive for action is not only unwarranted and undesirable, but useless. Panic or hysteria seldom results in constructive activity. Factual information may stimulate constructive public action. The public should know what public health workers are doing to promote radiological health and what more they think they ought to be doing.

Since we do not yet know at what point the harmful effects of prolonged, low-level exposure may outweigh the benefits of manmade radiation, we suggest that all unnecessary radiation exposure should be avoided. Consequently, much of our efforts in public health thus far are being directed toward finding what exposure is unnecessary and how it can be avoided.

Reducing X-ray Exposure

One of the major sources of radiation exposure today is the X-ray. If we can reduce needless exposure to X-ray without reducing its manifold benefits in the detection and treatment of disease, we have taken a significant step toward reducing the dimensions of the radiation exposure hazard. Much health agency activity in the radiological field is currently directed toward this goal.

For example, public health agencies for several years have been making a concerted drive to eliminate the use of the fluoroscopic shoe-

Dr. Price, chief of the Bureau of State Services, Public Health Service, delivered this address at a symposium of the American Association for the Advancement of Science, Indianapolis, December 30, 1957.

fitting machine. This machine serves absolutely no practical purpose. Moreover, if a child uses it each time he gets a new pair of shoes, he gets a considerable dosage of radiation over the years particularly since many of these machines deliver a scattered dose over a rather large part of the body. This is obviously a source of radiation that can be eliminated without the sacrifice of any beneficial result. The shoe industry has been cooperative. Shop owners, once they are fully informed of the facts, seldom show any reluctance to remove these machines. The main reason this type of shoe-fitter continues to be used is because there are not enough people, health officials or others, who have the information, the time, and the interest to work on the drive to eliminate this hazard.

Another example of unnecessary exposure is the indiscriminate use of the X-ray in tuberculosis surveys. When tuberculosis was more widely prevalent, communitywide mass X-ray surveys were justified. The early case finding from such surveys has unquestionably saved thousands of lives. There are still communities in the United States today where the prevalence of the disease makes mass X-ray campaigns desirable. However, there are other groups of people among whom the disease is so rare that the mass X-ray approach is no longer the best case-finding method. Consequently, the Public Health Service has recently recommended a more selective use of this procedure.

Interestingly enough, when this recommendation was publicly announced, it was interpreted by some as implying that mass X-rays were especially hazardous and that the Public Health Service opposed their use. This is an example of the emotional exaggeration that creates unwarranted fears and hampers constructive efforts to promote health objectives. Any general reluctance on the part of the public to accept diagnostic X-rays, when recommended by responsible authorities, would certainly be far more injurious to health than would the slight additional amount of radiation exposure. The vast majority of papers and other mass media made it clear that the individual X-ray in itself is not hazardous and that in areas where tuberculosis is prevalent mass X-ray surveys are still a valuable case-finding technique.

(Above) Without impairment of X-ray pictures, technicians adjust cones, filters, distance, and voltage so as to reduce radiation doses as much as 75 percent. The white strips on the model fluoresce under radiation to indicate exposure of strategic tissues, during demonstrations of X-ray techniques conducted by the Public Health Service. Dr. Walter Stahl points to charts (opposite page) which explain the value of these adjustments. Accompanying tables show the dose to different organs under various conditions.

(Top right) An aluminum plate absorbs soft X-rays, which lack energy to pass through the patient directly to the radiographic plate. Soft X-rays fuzz the X-ray picture and contribute an unnecessary dose to the patient. A cone, absent here, would further confine the dose.

(Below right) Too large a cone, or complete absence of a cone, permits beams intended for a chest plate to strike organs which should be protected. Even with a correct cone, irrelevant portions of the body may receive a radiation dose if the tube is too far from the patient.

X-ray film

A third example of the opportunity to reduce unnecessary exposure to X-ray lies in the reduction of the radiation doses delivered in medical and dental examinations. It is an unfortunate fact that many of the more than 160,000 X-ray machines being used in the healing arts today deliver a higher dose of radiation than is necessary. There is room for much improvement both in the machines themselves and in the techniques of their use. To drive home this point, our radiologists use a wax model taped and instrumented to show radiation dosage. They take a chest X-ray with typical equipment and employ a commonly used technique. Then, changing the cone of the machine, focusing more precisely, and making a few other adjustments, they take an equally useful film, but expose the monitored tissues to only 1/35th as much radiation.

Several studies now under way within the Public Health Service are designed to perfect techniques that will produce films of maximum value with minimum exposure and to provide better measurement of the doses delivered. Hand in hand with such studies, however, must go the training of technicians to make use of the equipment and procedures which are already available and which reduce substantially the radiation dosage received by both the patient and the operator.

Other studies are being carried out by public health personnel at all levels of government to reduce unnecessary X-ray exposure. As more physicians, dentists, and other members of the healing arts become aware of all that they can do to prevent unnecessary exposure, the X-ray hazard can be controlled. The problem is primarily one of research and of getting the findings of such research to professional groups, most of whom will readily understand their significance and apply them to their practice.

Measuring Environmental Radiation

The development of nuclear energy brings new significance to every effort to minimize exposure so that hazards may be balanced against the benefits of radiation not only in the healing arts but also in industry.

Therefore, along with drives against unnecessary X-ray exposure, health agencies are con-

New Radiological Health Division

On recommendation of the Surgeon General and approval of the Secretary of Health, Education, and Welfare, a Division of Radiological Health has been set up in the Bureau of State Services with Francis J. Weber, M.D., as chief. Dr. Weber, a commissioned officer of the Public Health Service, comes from Region 8, Department of Health, Education, and Welfare, Denver, Colo., where he was regional medical director.

cerning themselves with environmental sources of radiation.

Before he split the atom, man gave little thought to the background radiation in nature. Consequently, although we know that there is great variation in the background radiation of different localities, we have little information about what these levels are for any given area or for its air, water, or food. Obviously, it is necessary to have such information in order to determine how much radiation manmade sources are adding to the environment. Moreover, the time when we can obtain such data is fast slipping away. Ideally, these baseline studies should have been made before the first atom was split. Nevertheless, if we get this information as rapidly as possible, it will still be extremely valuable in helping us to make better health evaluations of exposure doses.

Baseline data are now being obtained on a limited scale. The focus of most of these monitoring activities is within the Atomic Energy Commission. However, the Public Health Service, in cooperation with State health departments and community groups, has operated for the past 5 years some 100 air and rain surveillance stations in order to measure community air pollutants, including radioactive pollutants. More recently, the Service has established about 40 stations for surveillance of water pollution. Here, too, analysis of collected samples includes radioactive pollution. The only food study in which the Public Health Service is currently participating is the collection and analysis of milk for strontium-90 and other radioactive elements. These studies are being conducted in five major milk shed areas.

The Food and Drug Administration is conducting other limited surveys. All of these baseline studies need to be expanded . . . now.

Baseline data are needed as a guide in the selection of reactor sites and as a gauge for determining how much and how rapidly radioactive waste from industry and from fallout is being added to the environment in any given area.

Such data may also prove helpful in the development of epidemiological studies. To date, studies of permissible radiation doses have been based primarily on observations of persons exposed to abnormally high radiation dosages and are, at best, estimates. In order to evaluate the public health significance of radiation, we need to devise means of measuring the far more subtle effects of prolonged, low-level exposure. Since the damage from this type of exposure extends over years and generations, the difficulties of the measurement task are too obvious to need delineation here. We place a high priority on such research. The information is needed not only to provide a better basis for establishing practical radiation dose limits but also to relieve the public of those exaggerated fears which inevitably occur when one is dealing with unknowns.

The increasing public awareness and concern about radiation exposure has been focused primarily on the matter of weapons testing. A far more important potential source of environmental radiation exposure is the rapidly growing number of power reactors based on nuclear fission. For this reason, long before the Shippingport, Pa., atomic power plant began operating in December 1957, health personnel, both Federal and State, were working closely with the designers of that installation. Radiation specialists from the Public Health Service and the Pennsylvania Health Department participated in planning the installation and operation of the waste treatment system at the Shippingport reactor. This collaboration includes baseline studies of the Ohio River system, the receiving stream.

The Shippingport operation has given industry, the Atomic Energy Commission, and the Federal-State health services an excellent opportunity to work out a practical pattern of

cooperation in the interest of public health safety. This cooperation will continue, and operating experience will provide an opportunity to test theory against practice.

A pioneering operation such as this naturally commands the careful and personal attention of highly trained experts. But what is going to happen as the industry expands? Will the same precautions always be taken? Traditionally, State agencies, and in most States, it is the health department, have assumed responsibility for seeing that every industry within their jurisdiction operates in such a way as not to endanger the health of the workers or of the other citizens of the community. Public health supervision of radiation sources in industry is therefore not a totally new concept. It fits into the existing pattern of industry and health department relationships. But it does present new challenges.

Will States and communities accept these challenges in time? To date, there are radiological health programs in only a few State health departments. All States need them. To date, only a few communities have any accurate idea of the sources and amounts of radiation to which their people are exposed. Every community should be taking this first step of assessing the radiation burden.

It will not long be feasible for the public to rely entirely on the users of radiation sources for assurance of community health protection. As nuclear sources of power begin to compete with conventional sources, there will undoubtedly be severe economic pressures to lower operating and capital costs. The public health agencies should be prepared to assure that such economies are not made at the expense of public health considerations.

Three Major Challenges

Summing up, radiation presents three major challenges to the public health profession. First, the public must be alerted to the need for greatly expanded radiological health programs which can provide security from fears that would hamper the constructive development of atomic industry and atomic medicine. Public understanding is basic because adequate radiological health programs require both legal au-

thority and financial support on a scale possible only when there is general public acceptance.

The second big problem is that of trained manpower. Radiological health is a specialized field with concepts, vocabulary, units of measurement, and sensitive instrumentation of its own. With the increase of radiation sources, there must be a corresponding growth in health personnel who have the training required to provide planning, surveillance, and other services. However, since highly trained specialists are produced slowly and since there is much to be done right now, the Public Health Service is providing practical training to the existing staffs of State and local health departments. This is done by courses and seminars designed to instruct trainers, persons who can conduct similar programs in their own areas. In addition, the corps of specialists needed as teachers and researchers must be increased. For this task, we look to our colleges and universities.

The third major need is research. I have touched upon the need to know the probable doses and the biological effects. The engineering field is presented with equally momentous challenges. For example, we have yet to find a satisfactory and economical method of disposing of high-level radioactive waste. The Atomic Energy Commission already has more than 65 million gallons of radioactive waste buried in tanks in the earth. As the Nation becomes dotted with nuclear energy plants, what is to be done with these high-level wastes? We are getting by at present with temporary expedients; we must seek long-range solutions.

In conclusion, I say again that, from a public health standpoint, radiation is still a preventable health hazard. I believe we can keep it so, if we act now. Since we recognize that all radiation is harmful and that its effects are cumulative and irreversible, the price of delay in the vigorous pursuit of research and control efforts might well prove to be intolerably high.

Graduate Fellowships in Public Health

Through projects in Massachusetts, Louisiana, and California, fellowships of \$2,500 are available for the second year of graduate study to social workers interested in the field of public health.

With assistance from the Children's Bureau, the health departments of the States have set up educational programs focused on social work practice in public health, in schools of social work. Participating are the schools of social work at Boston College, Boston University, Simmons College in Boston; Tulane University School of Social Work; and the University of California School of Social Welfare, Berkeley.

The University of California is also offering fellowships of \$3,600 for a year of supervised practice in public health following completion of the second graduate year.

Further information about these fellowships may be obtained by writing to the dean of any of these schools of social work. Applications should be made before April 15, 1958.

Foodborne Epidemic of Group A Beta Hemolytic Streptococcus

ROBERT E. FARBER, M.D., M.P.H., and FERDINAND A. KORFF, B.S.

A SUDDEN extensive outbreak of beta hemolytic streptococcal sore throat occurred in Baltimore, Md., during February 1957. The Baltimore City Health Department, investigating the outbreak, found that an estimated 600 individuals became ill following attendance of a charity luncheon by more than 800 people, mostly women.

Several members of the organization which sponsored the luncheon procured and prepared most of the food served. A commercial caterer and a restaurateur assisted in the preparation of some of the food. The menu consisted of egg salad, tuna fish salad, macaroni with cheese, cottage cheese with nuts and cherries, pickles and olives, ice cream, coffee, and cookies.

Epidemiologically, egg salad, the probable vehicle of the outbreak, is of interest because recent literature reveals three instances in which eggs were the vehicle of transmission for streptococcus infection (1-3).

The specific causative organism, group A, type 25, beta hemolytic streptococcus which was recovered from patients, is one of the types of streptococci reported as being nephrotoxic by Rammelkamp and others (4-7).

Epidemiological Studies

A questionnaire was distributed 1 week after the luncheon to as many people who had attended as possible. It soon became apparent

Dr. Farber is director of the bureau of communicable diseases, and Mr. Korff is director of the bureau of food control, in the Baltimore City Health Department, Baltimore, Md.

that it would be impossible to reach all of these people, since there was not a complete roster of the guests.

Because of the incomplete roster and because of the possibility that the questionnaires would be returned primarily by those ill, it was decided to base the epidemiological investigation primarily on the information obtained from the 96 members of the organization.

The questionnaire requested the following information: clinical details of the illness, time of onset of the illness, name of the attending physician, a history of foods eaten at the luncheon, a statement on whether any food had been taken home and, if so, who had eaten it and with what result.

Of the 96 members of the organization 6 had not attended the luncheon and 4 could not be found for questioning. Of the remaining 86 members, 60 had become ill with sore throats, giving an attack rate of 70 percent. Since it is reasonable to assume that the attack rate of this group is unbiased, it follows that of the 800 to 900 who attended the luncheon, some 500 to 600 probably became ill. This figure does not include secondary cases or those who were made ill by food brought home.

Figure 1 gives the frequency distribution in hours of onset of the illness following the luncheon. The shape of the curve, although slightly skewed to the right, is nevertheless consistent with the hypothesis of a common source epidemic.

By plotting the cumulative percentage of cases against the logarithms of the times of onset on normal probability paper (fig. 2) according to the method of Sartwell (8), the

points fall approximately along a straight line in a log normal fashion. From this graph the median incubation is estimated to be 31-32 hours, with 90 percent of the cases occurring within 65 hours following the luncheon. In the Fort Bragg outbreak (1) the estimated median incubation period was 38 hours, and in the Catskill epidemic reported by Sartwell (8) it was 56 hours.

Of the 60 members who became ill, all except 1 had a sore throat; 40, or 66.7 percent, had fever; 32, or 53.3 percent, had headaches; vomiting was reported by 11.5 percent, and 6.7 percent experienced diarrhea. There were no reported instances of a skin rash. There were no fatal cases.

Table 1 summarizes attack rates according to the food histories given by the 86 organization members. The outstanding observation is that, of 65 individuals who ate egg salad, 83 percent subsequently became ill and among the remaining 21 who did not eat egg salad, 29 percent became ill. For each food, the non eaters serve as a control for those who gave a history of

Figure 1. Frequency distribution of persons attacked, by time of onset of illness.

Figure 2. Cumulative distribution of persons attacked, by time of onset of illness.

eating. Where the attack rate differs significantly between the consumers and the nonconsumers, the foodstuff is said to be associated with the illness and is suspect as the vehicle of the illness. In the present investigation, egg salad and tuna fish salad are thus conjectured as possible sources of infection, egg salad showing a far higher association.

A factorial analysis, shown in table 2, indicates that among those who ate tuna fish salad, the attack rate was significantly determined by the consumption of egg salad. However, among those who ate egg salad, a history of tuna fish salad eating was not significant as a determinant of illness. These facts would seem to indicate that egg salad was the vehicle of the illness.

Further support for incrimination of the egg salad is provided by the analysis of the incidence of illness among husbands and other family members who were not in attendance at the luncheon, but who ate the leftover food brought home by the ladies. As shown in table 3, of those who ate the egg salad only, 71 percent became ill; whereas of those who ate the tuna fish salad only, 13 percent became ill. Of those who ate both egg salad and tuna fish salad, 59 percent became ill. There are certain limitations, of course, in this analysis. The in-

cidence of illness among members of the households who did not eat the leftover foods was not obtained. This information could have provided an estimate of the expected incidence in the absence of a history of exposure to suspected foods, either due to spread of the agent (secondary cases) or unconnected with the episode.

Investigation of the preparation of the foods strengthened the evidence that the egg salad was the vehicle of spread. The tuna fish salad and cottage cheese had been prepared by the caterer, whereas the egg salad had been prepared by the restaurateur. The tuna fish had been supplied in unopened cans to the caterer, and the mayonnaise was a well-known commercial brand in large unopened gallon jars. The cottage cheese was secured from one of the large milk plants in Baltimore City. The macaroni and cheese had been prepared at the luncheon and served hot.

The raw eggs for the egg salad were obtained from various sources by the ladies of the organi-

zation. In the homes of eight members they were hard-boiled and shelled by the ladies with the help of maids and others on Monday, February 4. The hard-boiled eggs were then collected from these homes and delivered to the restaurateur some time on Tuesday, February 5, the day before the luncheon.

At the restaurateur's, on the evening of February 5, the peeled, boiled eggs were cut by machine and mixed with washed, cut-up celery. The room temperature was said to be between 78° to 82° F. Mayonnaise from the original containers, seasoning, and a quantity of mashed potatoes were added. This mixture was excessively handled, being run through the grinder three times, and then put in plastic bags of approximately 25 pounds each. These were sealed and placed in the restaurant refrigerator for approximately 9 hours at a temperature reported as 34° F. There are indications that this food was not completely chilled until after many hours storage in the refrigerator.

for plating in 24 hours. The organisms isolated were tested for biochemical reactions and in the case of the pigmented staphylococci, the Stone's agar and coagulose reactions were tested.

Beta hemolytic streptococci were not isolated from any of the food samples, but the egg salad was heavily contaminated with *Escherichia coli*; hemolytic, pigmented staphylococci; and alpha streptococci. From the cottage cheese a hemolytic pigmented staphylococcus and an alpha streptococcus were isolated. Only an alpha streptococcus was isolated from the tuna fish salad.

Four weeks after the luncheon 9 throat cultures were taken at random from 9 women who had had acute sore throats following the luncheon. Of these, three were positive for a group A, type 25, beta hemolytic streptococcus. At the time the cultures were taken, all of these ladies were asymptomatic and had apparently fully recovered from their acute illness. None of the nine had been cultured previously in the investigation.

Thus, group A, type 25, beta hemolytic streptococci were isolated from 3 of 6 attendants at the luncheon who were cultured 2 days later, from all 3 food handlers cultured 5 days after the luncheon, who prepared the egg salad, and from 3 of 9 attendants at the luncheon who were cultured 4 weeks later.

Complications

Since the causative organism, group A, type 25, beta hemolytic streptococcus, had been cited as being nephrotoxic, a survey was initiated to estimate the frequency of nephritic as well as other complications. The survey was timed to coincide with the maximum time interval between the acute sore throat and the onset of possible nephritis, that is, 21-28 days (9). Physicians practicing in the area where the majority of the patients lived were questioned and alerted to this possibility. Questionnaires were sent to 47 of the physicians known to have treated some of the patients. Of these, 33 responded and reported that they had treated a total of 310 patients. None of these patients was reported to have had any signs of nephritis within 5 weeks after the acute attack; 51 of the 310 had recurrences of sore throat after ap-

parent initial recovery. Other complications reported were 3 cases of sinusitis and 3 cases of otitis media.

In addition to the questionnaires to the physicians, single urine specimens were obtained by the public health nurses of the Baltimore Health Department from 97 of the ladies, including members and nonmembers, who had had sore throats. The specimens were obtained during the fourth week following the acute illness. These 97 specimens were tested within 6 hours of collection for the presence of albumin and red blood cells. All of the tests were negative except one which showed a two-plus albumin and 1 to 2 red blood cells per high-power field. In this latter case, the patient's personal physician was contacted and his further investigation revealed no evidence of nephritis.

Discussion

The estimated primary attack rate for this foodborne streptococcus outbreak, 69.8 percent, was high compared with other reported outbreaks. The Fort Bragg attack rate was 41.7 percent, of which 91 percent were primary cases and 9 percent were carriers (1). There are several possible explanations for this difference. The causative organism in the present outbreak may have been new to this community so that the number of previously immune individuals was low. Since the typing of streptococci is a recently adopted procedure and not regularly performed, there is no evidence to refute or substantiate this possibility.

A more likely possibility derives from the fact that both the health department investigators and the private physicians gained the impression that several of the so-called patients were not truly infected but merely had psychosomatic complaints. In addition, the fact that only two-thirds of the reported patients had fever seems unusually low for streptococcal sore throat and therefore supports this contention.

Consistent epidemiological evidence suggests egg salad was the vehicle for the disease: first, the epidemic curve indicated that the reported disease was due to a common vehicle; second, the analysis of attack rates according to foods

Table 3. Attack rates, not present at luncheon but eating food brought home

Food taken home	Number eating food	Number ill	Percent ill
Egg salad only-----	38	27	71.1
Tuna fish salad only-----	15	2	13.3
Egg salad and tuna fish salad-----	21	12	57.1

Upon investigation of the food handlers at the restaurateur's where the egg salad had been prepared, it was discovered that one of them had been examined at a local hospital for severe cellulitis of his left hand on February 7, the day following the luncheon and 2 days following the preparation of the egg salad. The following is an abstract of his hospital outpatient record:

Present illness: Patient states that on several occasions he has had pus pimples on his hands. This time, the present episode began yesterday, and his left hand became swollen and sore. There are also pus pimples on the right hand.

Physical examination: Discloses erythema and edema of fingers of the left hand, and also hand itself is edematous. Increased temperature in area. Linear red streak up the flexor surface of left forearm and up the arm into the left axilla where there is a large axillary adenitis present.

Diagnosis: Pustular dermatitis, both hands; cellulitis, left hand; lymphangitis, left arm; lymphadenitis, left axilla.

No cultures from the food handler were taken at the hospital. Cultures from this man's hand and throat were subsequently obtained in the Baltimore City Health Department on February 11, 6 days after the preparation of the egg salad. In addition, throat cultures and hand cultures were taken on February 11 from 2 other food handlers who likewise were involved in the preparation of the egg salad. The report on these cultures will be discussed under the laboratory findings.

The food handler with cellulitis insisted that his hands were normal at the time of the preparation of the egg salad and that they did not become sore until 24 hours later. This fact is borne out in the above abstract from the hospital record where it is clearly stated that the infection of the hands began "yesterday," that

is, on February 6, the day after preparation of the egg salad. This information in the hospital record was given before there was any suspicion that a foodborne epidemic was involved. The previous occurrences of "pus pimples," according to the food handler, followed exposure to mayonnaise, vinegar, and certain detergents. They may have represented contact dermatitis.

Laboratory Findings

Six throat cultures were obtained from patients who had attended the luncheon. Four of these were taken by the health officer and two by a private physician on February 8, 2 days after the luncheon. These cultures were examined in the laboratories of the Baltimore City Health Department and typed at the Johns Hopkins School of Hygiene and Public Health. Five cultures were reported to have grown beta hemolytic streptococcus, group A, using the Taxos disk method. From the sixth culture an alpha streptococcus and a hemolytic, pigmented, coagulose positive staphylococcus were isolated. Further typing of the group A culture indicated that 3 of the 5 were type 25; one was untypable and the fifth culture was group C instead of the originally thought group A.

Throat cultures taken on February 11 from the 3 food handlers who had prepared the egg salad showed beta hemolytic streptococci, which were later typed as group A, type 25. It is of interest that the food handler with cellulitis of the left hand still had a positive throat culture in spite of 3 intramuscular injections of 600,000 units of penicillin, given on February 7, 8, and 11.

Cultures from the hands of these food handlers, including the one with cellulitis, were negative for beta hemolytic streptococci.

Bacteriological examinations of the samples of the egg salad, tuna fish salad, and cottage cheese were done as follows: 10 grams of each were emulsified in 90 cc. of sterile buffered distilled water. Serial dilutions were made and plated for total and coliform counts. A tenth of a cubic centimeter of the emulsion was plated on Teague's EMB, blood, tellurite glycine, and desoxycholate lactose saccharose citrate agars. Selenite enrichment broth was also inoculated

for plating in 24 hours. The organisms isolated were tested for biochemical reactions and in the case of the pigmented staphylococci, the Stone's agar and coagulose reactions were tested.

Beta hemolytic streptococci were not isolated from any of the food samples, but the egg salad was heavily contaminated with *Escherichia coli*; hemolytic, pigmented staphylococci; and alpha streptococci. From the cottage cheese a hemolytic pigmented staphylococcus and an alpha streptococcus were isolated. Only an alpha streptococcus was isolated from the tuna fish salad.

Four weeks after the luncheon 9 throat cultures were taken at random from 9 women who had had acute sore throats following the luncheon. Of these, three were positive for a group A, type 25, beta hemolytic streptococcus. At the time the cultures were taken, all of these ladies were asymptomatic and had apparently fully recovered from their acute illness. None of the nine had been cultured previously in the investigation.

Thus, group A, type 25, beta hemolytic streptococci were isolated from 3 of 6 attendants at the luncheon who were cultured 2 days later, from all 3 food handlers cultured 5 days after the luncheon, who prepared the egg salad, and from 3 of 9 attendants at the luncheon who were cultured 4 weeks later.

Complications

Since the causative organism, group A, type 25, beta hemolytic streptococcus, had been cited as being nephrotoxic, a survey was initiated to estimate the frequency of nephritic as well as other complications. The survey was timed to coincide with the maximum time interval between the acute sore throat and the onset of possible nephritis, that is, 21-28 days (9). All of the tests were negative except one which showed a two-plus albumin and 1 to 2 red blood cells per high-power field. In this latter case, the patient's personal physician was contacted and his further investigation revealed no evidence of nephritis.

Discussion

The estimated primary attack rate for this foodborne streptococcus outbreak, 69.8 percent, was high compared with other reported outbreaks. The Fort Bragg attack rate was 41.7 percent, of which 91 percent were primary cases and 9 percent were carriers (1). There are several possible explanations for this difference. The causative organism in the present outbreak may have been new to this community so that the number of previously immune individuals was low. Since the typing of streptococci is a recently adopted procedure and not regularly performed, there is no evidence to refute or substantiate this possibility.

A more likely possibility derives from the fact that both the health department investigators and the private physicians gained the impression that several of the so-called patients were not truly infected but merely had psychosomatic complaints. In addition, the fact that only two-thirds of the reported patients had fever seems unusually low for streptococcal sore throat and therefore supports this contention.

Consistent epidemiological evidence suggests egg salad was the vehicle for the disease: first, the epidemic curve indicated that the reported disease was due to a common vehicle; second, the analysis of attack rates according to foods

consumed implicates egg salad as the determinant of the sore throat; third, the analysis of attack rates among those who ate food brought home from the luncheon also points to the egg salad; and fourth, the causative organism was isolated from the throats of the food handlers who prepared the egg salad. The failure to isolate the organism from the egg salad may perhaps be explained by the fact that at the time food samples were cultured, the egg salad was at least 72 hours old, and the eggs themselves had been shelled approximately 96 hours. Presumably, any beta hemolytic streptococci that might have been present could have been overgrown with other organisms.

The inability to find the causative organism in the vehicle demonstrates the need for epidemiological investigation of all illnesses attributed to food, and the inherent limitations in inferences based solely upon the results of analyses of residues of food served. Food available for examination following any outbreak of illness is food that has not been eaten, and unless of liquid consistency a negative finding cannot be considered to refute the epidemiological findings.

The means by which the egg salad was contaminated pose an interesting question. If we accept the possibility that the man with cellulitis was a victim rather than the initiator of the outbreak, then we must look elsewhere for the mode of infection of the egg salad.

Any one of the ladies, or their maids and other helpers, who helped to prepare the eggs could have been a carrier of the streptococcus and could have coughed or sneezed inadvertently over her pile of shelled hard-boiled eggs. If the eggs were so inoculated and improperly refrigerated overnight in the ladies' homes, an ample growth of streptococci could have been present the next day when the eggs were delivered to the restaurateur.

The food handler could have been infected when he was putting the eggs through the cutting machine. An attempt to test this hypothesis was made. All the ladies involved in the preparation of the eggs were questioned, but they denied any infection or illness prior to the luncheon either in themselves or in members of their families. Of these 8 ladies all but 2 became ill 24 to 48 hours after the luncheon.

In addition, absentee records of schools in the vicinity were examined for evidence of sore throats. The only apparently pertinent information thus obtained was that the young son of one of the members was sick with a sore throat and fever 4 days before the luncheon. Investigation of this lead revealed that the whole family except the mother had been sick. The mother however could not be connected with the preparation of the eggs or any of the other foods served.

The positive throat cultures from the 3 food handlers at the restaurateur's taken on February 11, 1957, 5 days after the luncheon, could be explained by the assumption that each of these men sampled the egg salad during and after mixing. Investigation of this possibility revealed that two of the food handlers tasted some of the egg salad; the third could not be reached. Consequently, the question again arises whether these positive throat cultures are cause or effect.

Conclusions from the failure to find evidence of nephritis in 97 subjects must be guarded. A single urine specimen is not wholly adequate to rule out this condition, even when taken at approximately the time when nephritis would be expected to be present. The negative information secured from physicians treating over 300 patients must also be interpreted with caution. We may at least say, however, that the incidence of nephritis, if it occurred, was low. Only two cases of nephritis have been reported in the literature in association with type 25 streptococcus.

Apparently the secondary attack rate for this outbreak was low. Those private physicians who were questioned reported very few cases in other members of the families or the community except among those who ate the food served at the luncheon. Likewise, a review of the causes of absence from the schools in the area showed no marked increase in the number of acute sore throats. One possible explanation for the low secondary attack rate is the fact that many of the private physicians in the area gave routine prophylactic antibiotics to contacts of the primary cases. However, secondary attack rates appear to have been low in other foodborne streptococcal epidemics before antibiotics were used.

Even after taking into account the use of effective antibiotic therapy, the cases in this epidemic were impressively mild as contrasted with those of an earlier era when septic sore throat was attended by a considerable number of suppurative complications and a substantial mortality. This is consistent with the long-time trend toward reduced clinical severity of scarlet fever and, presumably, respiratory streptococcal infections.

Summary

In February 1957 a foodborne outbreak of streptococcal sore throat, estimated to have caused over 500 illnesses, occurred in Baltimore, Md. The attack rate was 70 percent among the 86 persons studied. The causative organism was a group A, type 25, beta hemolytic streptococcus.

Epidemiological investigation suggests that egg salad served at a luncheon was the vehicle, 83 percent of those who ate the food reporting illness. The source of the infection was not ascertained.

Although the search for nephritic complications was limited, no evidence was found to support reports of the nephrotoxic potential of this streptococcal type.

The Biophysical Society

The first national meeting of the Biophysical Society was held at the Massachusetts Institute of Technology in Cambridge, Mass., during February 5-7, 1958.

Founded in March 1957 in Columbus, Ohio, the society has defined its aim as the promotion of "a more complete biological science with emphasis on mathematically formalized theory and quantitative experimentation." The group hopes to achieve this goal by welding into a new scientific team experts from such fields as physics, biology, medicine, chemistry, mathematics, and engineering.

Intensively studied at the 1958 meeting were aspects of molecular biophysics, particularly microsomal particles and protein synthesis, and muscle proteins and contractile mechanisms. Papers were presented by specialists drawn from the United States and abroad with the assistance of the National Science Foundation.

TPI and TPCF Tests On 2,000 Patients Difficult to Diagnose

AD HARRIS, VIRGINIA H. FALCONE, B.S., LEWIS S. PRICE, and WILLIAM J. BROWN, M.D.

SINCE January 1, 1955, the Venereal Disease Research Laboratory of the Public Health Service has offered a *Treponema pallidum* immobilization (TPI) testing service on a nationwide basis to all physicians through the laboratories of State and Territorial departments of health. The Venereal Disease Research Laboratory has received from State laboratories requests for TPI testing of approximately 100 serums per week since commencement of the service (1, 2). During a part of this period, the *Treponema pallidum* complement fixation (TPCF) test also was used—experimentally and as a research tool. From July to December 1956, both these procedures were used on all serums submitted for TPI testing, and in January 1957 the TPCF test was made an integral part of the TPI testing service.

All serums submitted for TPI testing have been tested first with the TPCF procedure since January 1957. Only those serums that are not nonreactive in the TPCF test are then tested with the TPI procedure. When both tests are performed, the completed report identifies each test by name and lists the results obtained in each.

This report presents analyses of results obtained with TPI and TPCF tests on 2,000 serums tested during the period from July to December 1956, when all serums were being tested with both procedures, and relates these findings to the patient data and medical opin-

ions submitted with the serums. Serums were received from more than 1,300 physicians in 47 States and Territories, so they probably represent a fair cross section of the diagnostic-problem patients of the average physician. The patients included 1,255 females (62.75 percent) and 745 males (37.25 percent). This percentage distribution by sex is approximately the same as has been noted since the TPI testing service was introduced, and it may indicate that the diagnostic problem in regard to syphilis is occurring approximately twice as often in female as in male patients (3).

Methods

Serums. Specimens submitted for TPI testing service are received from the State and Territorial departments of health laboratories, accompanied by completed clinical data sheets. The clinical data sheet, in addition to identifying the patient, lists blood and spinal fluid test reports, any history of treponematoses and treatment given, history of several conditions or infections known to be associated with biologic false-positive (BFP) reactions, and finally, the opinion of the attending physician as to the probable diagnosis of the patient at the time the blood is submitted. The stipulations for the acceptance of specimens for this service are that they be sterile serums from diagnostic-problem patients with no history or clinical evidence of syphilis or with suggestive evidence of untreated syphilis.

TPI Test. The TPI test was performed according to the Nelson technique (4, 5) as modified in later publications by the Venereal Disease Research Laboratory (6-9). Only those serums which, after treatment with penicillinase, produced less than 70 percent motility in the control tube were reported as inconclusive.

TPCF Test. The qualitative TPCF test was performed according to the technique described by Portnoy and Magnuson (10). Antigen was obtained from the Venereal Disease Experimental Laboratory, Chapel Hill, N. C. An anticomplementary report was recorded on those specimens that were anticomplementary in qualitative testing and insufficient in quantity to allow preparation of dilutions for retesting as prescribed in the technique.

Mr. Harris is director, Mrs. Falcone is a bacteriologist, and Mr. Price is administrative officer, Venereal Disease Research Laboratory, Venereal Disease Branch, Communicable Disease Center, Public Health Service, Chamblee, Ga. Dr. Brown is chief of the Venereal Disease Branch, Communicable Disease Center, Atlanta, Ga.

Discussion

Specific test results obtained with the TPI and TPCF tests on 2,000 serums (745 from male patients and 1,255 from female patients) are shown in table 1. Several observations may be made from these data. The TPCF test was slightly more reactive for this donor group than was the TPI test. Although 42.5 percent were reactive to the TPCF, while 47.7 percent were reactive to the TPI test, the reactive plus weakly reactive results totaled 51.0 percent for the TPCF and only 49.8 percent for the TPI test. Conversely, the percentage of nonreactive findings was greater with the TPI test (50 percent) than with the TPCF test (48 percent). The percentage of nonreactive results in both tests was higher for serums from females (TPI 54.4 percent and TPCF 51.2 percent) than for the specimens from males (TPI 42.6 percent and TPCF 42.7 percent). As indicators of probable false-positive reactions in other tests for syphilis, the nonreactive results in these tests suggest that the proportion of probable biologic false-positive reactors is higher in female than in male patients.

Only 20 (1 percent) of the 2,000 serums were reported as anticomplementary in the TPCF test (see "Methods") and only 3 serums (0.2

percent) were reported inconclusive in the TPI test.

Actual agreement between the results obtained with the TPI and TPCF tests is not as great as is indicated by the total percentage of reactive plus weakly reactive results for the two tests. One hundred and one serums (5.0 percent) that were nonreactive in the TPCF test produced reactive or weakly reactive results in the TPI test. One hundred and thirty-one serums (6.5 percent) that produced nonreactive results in the TPI test were either reactive or weakly reactive in the TPCF test. Direct disagreement of results obtained with the two tests was produced, therefore, in 11.5 percent of the 2,000 specimens. Inclusion of anticomplementary and inconclusive findings brings the non-agreement total to 12.7 percent.

Complete serologic agreement of these two tests was obtained in 1,745 (87.3 percent) of the serums in the series. Both tests were reactive or weakly reactive in 887 (44.4 percent), and both were nonreactive in 858 (42.9 percent) of the specimens tested.

Since the TPCF test is now being used as a screening procedure for the TPI testing service, the 101 serums showing nonreactive results in the TPCF test but with some degree of reactiv-

ity in the TPI test are of most interest. Table 2 shows that these serums were from 18 patients considered to be syphilitic, 71 patients considered to be biologic false-positive reactors, and 12 patients for whom no clinical opinion had been given. The group includes 24 patients with some history of syphilitic infection and 77 patients without positive history or physical findings of infection. Distribution in this group as to sex, history of previous syphilitic infection, and present diagnosis is not unlike

that in the remainder of the 2,000 patients in this study. One significant difference noted of this group, however, was the number of weakly reactive TPI test results. Twenty-five (25 percent) of these 101 serums produced weakly reactive TPI test findings as compared with only 41 (2 percent) of the total 2,000 serums tested.

Seventeen hundred and fifty-four of the serums were accompanied by data sheets indicating the clinical impression of the submitting physician as to whether the patient was a biologic false-positive reactor or had syphilis. Comparisons of test results obtained on specimens in these two categories are presented in tables 3 and 4. No clinical opinion was indicated on the data sheets for the remaining 246 serums.

Of the 1,407 serums from patients listed as probable biologic false-positive reactors (table 3), 47 percent were nonreactive to both the TPI and TPCF tests. Results from either test alone were in slightly closer agreement with the medical opinion that these specimens were from BFP reactors, since 54.3 percent nonreactive results were obtained with the TPI test and 52.0 percent were produced in the TPCF test. Of the 1,407, 40.3 percent were either reactive or weakly reactive in both the TPI and TPCF tests. The group of specimens from females showed closer agreement with medical opinion

than specimens from males. Nonreactive results were produced by TPI in 58.8 percent, and by TPCF in 55.5 percent of the serums from female donors, whereas each test produced nonreactive results in 45.5 percent of the serums from males. This may reflect some factor, present in the female, that is responsible for an increased percentage of BFP reactions.

Of the 347 specimens from patients currently diagnosed as syphilitic (table 4), 61.7 percent were reactive or weakly reactive in both tests, while 25.6 percent were nonreactive in both tests. Again slightly closer agreement with medical opinion was shown by the results of each test considered independently, since 67.2 percent reactive results were produced in the TPI test and 68.3 percent were obtained in the TPCF test. Here no significant difference between reactivity in either test of serums from male and female donor groups was noted.

Approximately 5 percent of the serums in this study produced TPI reactions (reactive or weakly reactive) and would have been missed if the TPCF nonreactive serums had not been tested further. However, 6.5 percent of the serums were reactive or weakly reactive in the TPCF test and produced nonreactive findings in the TPI test. It is estimated from these bases that the TPCF test, when used as a screening procedure for the TPI test, may detect (in-

cluding anticomplementary findings) approximately 90 percent of the serums that will produce reactive or weakly reactive findings in the TPI test, although a larger total number of reactive plus weakly reactive TPCF test results may be obtained. The percentage of agreement between results obtained with the TPI and TPCF tests reported here would not necessarily be similar to findings produced by testing groups of specimens selected in a different manner.

Summary

Results obtained with the TPI and TPCF tests on 2,000 serums from diagnostic-problem patients were in agreement on 1,745 serums (87.3 percent).

The greater proportion of nonreactive results produced by serums from female patients in both or either of the treponemal tests is an indication that biologic false-positive reactions may be more prevalent among female patients.

PHS exhibit

The Domestic Migrant Worker

To encourage community effort in meeting the health problems of domestic agricultural migrants on a continuing basis, information is supplied through a Public Health Service exhibit.

The exhibit consists of maps, charts, and photographs, illustrating the major routes traveled, important work areas, typical housing, and health conditions. It gives examples of organized effort in making health services available to the migrants who follow the crops each year. The exhibit is designed for display at national, regional, and State conferences, and in other places where interested people gather together.

Specifications: A 3-panel exhibit on legs, 7 feet high, total weight 377 lbs., including the packing crate; back panel, 4' x 6'; each of the side panels, 4' x 3', attached to the center by hinges. Lighting fixtures fit into each of the panels through slots at the top, and the three 150-watt reflector floodlights can be connected with a single outlet. Available through the Division of General Health Services, Public Health Service, U. S. Department of Health, Education, and Welfare, Washington 25, D. C.

are we getting public health in tune with the times?

"Be they pessimists or optimists, public health workers everywhere agree that these are times of change and that the future of public health is either beset with or holds promise of unprecedented challenge. Fortunately, there is today a ferment in public health. . . . The frustrations, the disappointments, the dissatisfactions and discontentments are, in my opinion, the precious yeast so essential to constructive ferment. They are basic to the evolution of new knowledge and new understanding which can lead to greater attainment. . . . Although science can show us how to achieve our ends, it is a sobering fact, but a heartwarming and human one, that for motivation and purpose we must seek guidance elsewhere—in faith, in fellowship, in our relationships, and in our public policy pronouncements. It is in guidance in these all-important areas that our Association has the potential for serving us so well."

JOHN W. KNUTSON, D.D.S., Dr.P.H.
President, American Public Health Association
From the presidential address at the
Eighty-fifth annual meeting, November 11, 1957

SUMMARIES OF SELECTED PAPERS
from the 85th annual meeting
of the
AMERICAN PUBLIC HEALTH ASSOCIATION
and related organizations
held at Cleveland, Ohio
November 11–15, 1957

The APHA Conference Report

With the assistance and cooperation of the authors, the staff of *Public Health Reports* has summarized some 70 of the papers presented at the 85th annual meeting of the American Public Health Association and related organizations in Cleveland, Ohio, November 11-15, 1957.

Summaries selected for publication in the following pages are intended to present information which may not otherwise have been given adequate notice. Omitted from these selections are papers which were known to have been scheduled for early publication in the *American Journal of Public Health*; papers whose authors provided no copies for this

journal; and papers which, for one reason or another, did not seem suited to summarization.

No papers on laboratory methods are summarized here because of the understanding that they would have early publication, at least in brief form, in the APHA journal.

Other papers presented at the conference are under consideration for publication in subsequent issues of *Public Health Reports*. The February issue carried papers given at the meeting of the health officers section with the American College of Preventive Medicine.

Names of sections and some of the affiliated organizations represented at the conference are listed below.

Current Needs . . .

Effective Health Department Uses Community Resources

Observing that health officers generally consider the community or the political subdivision they serve as their patient, Dr. Ellis D. Sox, director of public health for the city and county of San Francisco, touched briefly on current administrative needs.

Most important, said Sox, we must remove from our thinking the effects of "ancestor worship" and make administration a moving and changing force toward the solution of public health problems of every community, every State, and the Nation.

Motivation of the patient—the community, that is—to accept recommended treatment and the ability of the health officer as administrator to use all necessary resources in the most effective and efficient manner possible are two other important factors, according to Sox. He believes that the health officer must use more and more of the skills currently used by private industry and business in order to make his official activities effective.

In creating recognition among the public of needs for corrective action, the health officer must adopt the techniques of modern communications, he advised. To achieve recognition and correction of such public health problems as poor mental health, alcoholism, and suicides, he must use also the information and know-how available from specialists in sociology, cultural anthropology, and economics.

Sox advocated the substitution of an authoritative approach for an authoritarian approach "so that the health officer may more effectively cooperate with law enforcement agencies, traffic enforcement agencies, urban renewal agencies, planning commissions, and rehabilitation and employment services."

This approach is not strictly that of the scientist, unless it be the social scientist, he said.

Conflict of Interests Demands New Approach

Unlike the communicable diseases, many modern public health problems raise a conflict between protection of the public health on the one hand and the uses of modern technology on the other, or, what is even more complex, a conflict among various public health interests, according to Frank M. Stead, chief of the division of environmental sanitation, California State Department of Public Health.

In the first category he listed medical, research, and industrial uses of nuclear energy; insecticides "so powerful that a few ounces are capable of killing all the insects in an acre of land"; and air pollution, particularly smog, the byproduct of petroleum when it is burned as fuel.

As an example of the second type Stead mentioned the various uses of water. "Outdoor recreation on water is a public health asset," he observed, "yet at the same time recreational use of water supply reservoirs runs counter to the classical principle of giving the highest possible protection to domestic water supplies. Reclamation of sewage to conserve both water and organic material could greatly reduce the pollutional load on streams and salt water recreational areas, but the re-use of such water and organic material carries with it public health risks. . . ."

Modern hazards cannot always be attacked as unmixed evils, Stead emphasized.

The solution lies in the highest possible degree of reconciliation of opposing interests, if they are valuable to society, asserted Stead.

It has been a reasonable policy to seek eradication of communicable

diseases, such as smallpox, plague, typhoid fever, malaria, and syphilis. But the practical value of radiation, insecticides, or materials causing atmospheric pollution is such that it is not wise to seek complete eradication of these hazards if that were possible. The end to be sought, he said, is control, rather than absolute protection. As a result, public health agencies today are deeply engaged in complex evaluation and planning.

Population Increases, Shifts Dictate New Activities

Implications of population changes, such as the increase in the oldest and youngest age groups, the geographic irregularity of the increases, and the rural-urban shifts, were discussed by Dr. John J. Hanlon, director of public health services of the city of Philadelphia and chairman of the department of preventive medicine and public health, Temple University School of Medicine.

These changes, he said, have occurred "with dramatic suddenness and with all the subtlety of a sledge hammer." Hanlon mentioned as outstanding for public health consideration the following items, none of them new, he said, but all deserving emphasis.

- The vast swarm of children appearing demands reevaluation, revamping, and extension of a number of activities, such as the well-child clinics and school health education.

- The growing number and proportion of individuals of advanced age dictates a change in thoughts and activities and development of truly fruitful services and facilities for this group. Above all, it is necessary to discard the idea that senility, infirmity, and incapacitation are synonymous with aging.

- The shrinking size of the middle age groups, the most productive social component, and the growing disparity between men and women in length of life suggest specific,

concerted attention to the wage-earning male.

All of these and other problems, Hanlon asserted, emphasize the need for serious effort to improve the quantity, quality, and distribution of personnel and facilities required to serve these needs.

For public health and medical training, Hanlon suggested that the cost of schools be shared through support not only by the Federal and State governments but also more and more by industry. He believes such sharing is fully justified, first, because the schools actually serve regional, national, and, indeed, international interests; second, because of the increased range of movement of the population; and third, because the schools serve what is now essentially an industrial culture.

With these and other factors in mind, Philadelphia is currently experimenting with standards and formulas for more exactly determining and measuring needs and priorities, Hanlon reported.

Community Organization, Key to Health Progress

Effective community organization is a key to progress in community health, according to views expressed by Sewall Milliken, department of public health, Yale University.

Starting with the premise that the "most crucial problem today is the ever-widening cultural lag between scientific health knowledge and the application of this knowledge by communities," Milliken emphasized community organization as a corrective method.

The three main ingredients in community health progress are research, education, and service, he said, explaining that keeping these three properly related is the job of community organization.

Milliken pointed out further that community health groups are usually coordinated by one or more professional health groups or voluntary or official agencies who have initiative.

As examples of sound community organization, Milliken mentioned the Cincinnati Health Federation, the Cleveland Health Council, and the Metropolitan Health Council of Columbus, three of the oldest community health councils. Such councils provide the setting and the opportunity for professional groups, voluntary and official agencies, and hospitals and other institutions to participate in cooperative health evaluation and planning, he said.

There is great need, according to Milliken, to inject this health council experience into curriculums and training courses to prepare individuals for specialized executive, administrative, and educational work.

Too often in the past, health programs have been established on the basis of personal opinion or hasty observation, he noted. In too many communities no money is set aside for fact finding and for systematic evaluation of future needs and developments.

Milliken believes that communities must devote time and money to fact finding and to studies of health needs and resources. The many demographic changes alone necessitate such action, he contended.

States and Localities Lag in Research

State and local health departments are not contributing adequately to progress in public health through research, contended Dr. Albert V. Hardy, director of the bureau of laboratories, Florida State Board of Health.

Few State or local health departments are approaching today's needs in the spirit of investigation that brought success in the control of communicable diseases, he said. In contrast to the activities of those concerned with the individual patient, Hardy observed little vigor in public health research by State and local health departments, which are experienced in the study of populations and which have ready access

to communities. The result is a lack of adequate evidence to develop a distinctive public health approach to modern conditions.

Hardy pointed out that the Federal Government supports public health research through grants administered by the Public Health Service.

"Public health workers, accustomed to categorical grants and unfamiliar with the exacting methods prescribed by law for the review of research grant requests, have been slow to seek supplementary support from this source," he said.

To substantiate this statement, he gave the following figures: In the years 1951-56, of 15,342 research grants totaling almost \$162 million only 66 (0.6 percent) amounting to about \$1½ million (0.8 percent) went to State and local health departments.

This lack of participation was the result, not of a low approval rate, but of a low request rate, Hardy maintained.

Research in the new fields of public health needs to be accepted on the same terms as epidemiological investigation of communicable diseases, he declared.

Hardy noted that the Association of State and Territorial Health Officers recommended in 1955 that health departments assign responsibility for research planning to a person or a committee.

Florida, he reported, has designated a State coordinator of research and plans establishment of divisions of research and program development in a number of local health departments. The first is in the Dade County Health Department.

Social Scientist Itemizes Felt Health Needs

Health needs recognized by the public were identified and described by Donald G. Hay, a social science analyst of the U. S. Department of Agriculture.

Public awareness of existing local

HEALTH CARE NEEDS

health services, he observed, is rooted in their involvement in such services.

From the results of several public opinion surveys, most of them conducted in rural areas by land grant colleges or the U. S. Department of Agriculture, Hay listed the following as needs recognized by the public (see table also):

- Additional health care personnel and facilities, particularly physicians.
- More effective organization of health care resources: better spatial distribution of services, willingness of physicians to make house or night calls, expansion of home nursing services, reduction in waiting time in the physician's office, and more effective communication between physician and patient.
- Improved environmental health.
- Greater emphasis on preventive health care.
- Further development of voluntary health insurance.

With regard to health insurance, the studies revealed a felt need for more consumer education on both "the financial protection available

and how such a financing mechanism serves to make the rapid advances of health care available to people," Hay said.

From similar studies, Hay reported the following observations concerning the public's knowledge of existing public health services:

- About three-fourths or more of the households know about their local health department.
 - From one-twentieth to one-third do not know of any services provided by their local health department.
 - The services most frequently reported as "important" are vaccination and immunization, chest X-rays, sanitation services, and maternal and child health services.
 - Usually more people indicate that they have used services available in local health departments than report having used the department.
- "Improved two-way communication between the public and the health agencies and continuing efforts to step up active participation by the people in planning and developing programs," were Hay's concluding recommendations.

Suggests Functional Study For Nurse Recruitment

Study of functions and services is one approach to the recruitment problem in the Philadelphia Department of Public Health's division of public health nursing, according to Madelyn N. Hall, director of the division.

Believing that application of all available scientific knowledge to the problem might produce solutions, Hall emphasized the need to do more than look for "as many seeds as one can find." The kind of seeds, the fertility and nourishment of the soil, and the planting methods will determine the recruitment yield, she said.

Characteristic functions of the public health nurse include health teaching, health counseling, epidemiological investigation, and interdisciplinary planning, as well as the practice of nursing techniques.

Time and activity studies, Hall reported, revealed that this academic definition of function was being applied only to a limited extent. As a result of the studies, a

Summary of health care needs recognized by the public¹

Survey area and date	Number of households reporting	Percent of households expressing need for—					
		More physicians	More dentists	More hospitals or clinics	Improved environmental health	More preventive care services	Other needs

³ Not ascertained.

number of questions had to be answered and a number of steps had to be taken.

The first question concerned service: What are the service responsibilities of the official agency and what are those of the voluntary agency?

Hall termed the traditional view of these responsibilities provincial. Responsibilities have been defined on the basis of the source of income rather than on the basis of the indivisibility of public health practice, she maintained. Responsibilities have been agreed upon to prevent duplication of service rather than to provide an integrated service.

As an illustration of how it should be, she cited Philadelphia's approach to the impending onslaught of Asian influenza. Representatives of six voluntary and official agencies and two professional organizations developed a plan of coverage for the city, she said. All nursing resources are pooled, and supervision is provided by qualified personnel of any one of the participating agencies.

Integration of services, however, is not the complete answer, she observed, listing the following additional questions: What services should be provided? How complete a population coverage can one expect? How do we deal with the major types of changes which are going on in the modern world?

Barriers to answering these questions include mandates from public officials who control the purse strings, vocal community pressures and lack of agreement by medical personnel immersed in their own specialties.

Hall considers the factor of services crucial. How can one know what staff to look for if one is not certain of the kinds and extent of services? she asked.

However, with only partial knowledge of these matters, perhaps the problem can be tackled from the standpoint of characteristic functions, she suggested. She mentioned improvements in training of public health nurses realized through this approach.

Disability Pension Called Obstacle to Rehabilitation

The pension, when its continuation is dependent on proof of disability, is a primary obstacle to rehabilitation, asserted Dr. Dean W. Roberts, executive director, National Society for Crippled Children and Adults:

The worker who incurs a severe disability has had an experience that may shake his confidence in himself and in the world in which he lives, Roberts explained. He faces the alternative of fighting a difficult and at times discouraging battle to overcome his disability and regain independence or of withdrawing into the protection of dependency with its shattering effect on human personality and dignity.

"Some argue," he continued, "that the disability pension provides a secure economic base from which the disabled person can work toward rehabilitation. Others, however, and many experts in rehabilitation among them, hold that as long as a man's bread-and-butter income hinges on his maintaining proof that he is totally disabled, only the rare individual will . . . turn his back on the small but secure pension and fight for economic independence in a competitive society."

Considering the current status of rehabilitation efforts, Roberts observed that rehabilitation techniques are being applied relatively effectively to children and to adults with a vocational objective, but not to the severely disabled who have no vocational objective. The aged disabled in particular are being neglected, he said.

Roberts considers this situation a direct reflection of State and Federal laws, which in turn reflect the attitudes of the public.

The severely handicapped who are beyond the reach of substantial rehabilitation could achieve a large degree of self-care if the proper services were available, he argued. Such a program would be justified not only from a humanitarian standpoint but also because it would reduce the large burden of custodial care and would free professional personnel now tied down with such care.

The time has come, he declared, when the philosophy and practice of rehabilitation must be applied by all physicians and in all hospitals and nursing homes rather than by a few specialists working in a few centers.

Additional areas for improving rehabilitation work are motivation of the patient and coordination of services, according to Roberts.

School Health . . .

How Health Teaching Gains Status and Support

Health teaching often lacks status and public support, although no other area of the school curriculum, except American history and citizenship, has received more legislative backing, asserted Dr. Bernice R. Moss.

Moss, public health adviser, Program Development Branch, Division

of General Health Services, Public Health Service, pointed out that laws in many States require the teaching of hygiene, sanitation, disease control, and the effects of alcohol and narcotics.

Within the school, however, health teaching is often a stepchild; it lacks the academic tradition of other subjects and is often confused with physical education, first aid, driver training, or family life

courses. Perhaps health education lost some of its academic status when the term replaced the older ones, hygiene and physiology, stated Moss.

She outlined how health teaching can gain status and public support to become a potent force, enriching the lives of children and improving the community.

Health education flourishes in schools where an administrator, convinced that it is essential to the curriculum, provides for academic credit, classrooms, teaching materials, and above all, a trained teacher.

Ultimately the worth of health teaching in both elementary and secondary schools rests with the trained teacher, Moss stated.

Ideally, the elementary teacher is a generalist who includes health education in her total teaching assignment, who is aware of children's health needs and interests, and who motivates behavior in accordance with acceptable biological and social patterns.

The secondary school teacher treats health education as an applied science. She draws from the physical, biological, and social sciences the concepts important to human survival, development, and adjustment. Not just anyone can teach health, Moss declared. Skill in instilling these concepts in adolescents demands training and insight.

Where administrative support is coupled with teaching competence, health education achieves status in the students' minds and through them, in the community. The youth whose behavior is improved, whose intellectual curiosity is aroused, pleases his parents. He is the best argument for health teaching, and he builds understanding and support for it.

Community Interest

Where schools do little health teaching, someone or some group may bring about a change. The parent-teacher association, the county medical society's school

health committee, the community health or welfare council, or some influential citizen can request information about health teaching from the school superintendent or principal. Interest in improving health teaching and the willingness of a community group to work with the schools can lead to constructive changes.

The public school curriculum is responsive to the will of the people, stated Moss. But care must be taken to emphasize the broad health needs of the child and the community. Piecemeal education can result from a group's pressure tactics or insistence that a particular topic be added to the curriculum.

People must understand that no magic formula will protect life and promote health, Moss asserted. The health concepts and behavior of a people grow from their culture, and children reflect their parents' attitudes and beliefs. With enlightened public support teaching can be changed. Status will accrue to health education as it proves itself in the lives of children and the improved health of the community.

Mental Health Programs In Schools Evaluated

Mental health programs in the elementary and secondary schools urgently need an appraisal of their results, clarification of the anxiety factor in growth and motivation, and closer cooperation between behavioral science specialists and teachers, according to Dr. John I. Nurnberger, chairman, department of psychiatry, and director, Institute of Psychiatric

Research, Indiana University Medical Center. He ascertained these needs by scrutinizing current practices in educational mental hygiene.

Appraisal Needed

Merely stating that the mentally healthy student is an educational goal is not enough. A skeptical appraisal of present practices to test their basic hypotheses is needed, Nurnberger stated. He questioned whether students participating in group discussions, counseling experiences, and other mental health activities really become more stable, creative, productive, and conscientious persons.

After 15 years' emphasis on children's social, cultural, and emotional needs, is today's youth more anxiety-free and emotionally stable? Why has there been no substantial decrease in the incidence of juvenile and young adult social deviants? Nurnberger questioned.

He pointed out that the information for assaying the mental health of any segment of the school population has not yet been collected and that such information may amplify and correct present mental health criteria. School mental health projects as reviewed in 1951 by the Committee on Preventive Psychiatry of the Group for the Advancement of Psychiatry have, as a common goal, improvement of the child's emotional maturation to enable him to function effectively.

The teacher's attitude is vitally important in this process. She must be tolerant and permissive so that the student can readily accept and appreciate behavior and its determinants in himself and his peers. The teacher-pupil relationship should de-

Bold Approach

If we continue merely the routine activities of the past, the health officer will be merely a cog in an essential but undistinguished administrative machine; only with a bold approach to meet the new demands of the time shall we earn the sense of real achievement which comes to the pioneer.—C. E. A. WINSLOW.

velop a more tolerant superego, according to the committee report.

The more tolerant the superego becomes, it is asserted, the more insight into motivational factors is developed, and the greater the resultant relief from anxiety. Thus the student ego will be strengthened, it is reasoned, and the child should enjoy a greater degree of adaptability.

But Nurnberger questioned whether maximal freedom from anxiety is necessary and desirable for student maturation, and whether the student so prepared actually becomes stable, productive, or socially responsible.

If the answer to these questions is yes, it then follows, Nurnberger maintained, that emotional maturation and ambitious aspirations prosper without anxiety. He questioned the proposition that personal standards of behavior should be leveled to bring a student closer to his peers.

He also asked whether such leveling of standards was worth while if its aim was to alleviate anxiety.

American culture may have developed as aggressively and productively as it has partly because restrictive behavior standards forced people to sublimate their sexual, aggressive, and hostile urges, Nurnberger stated.

Observing a great difference between applying knowledge toward the better understanding of others and applying the same knowledge toward control or complacent acceptance of self, Nurnberger questioned school mental hygiene programs which casually substitute common custom for more exacting models of individual behavior.

Teacher's Function

Nurnberger discussed other issues, centering on the teacher, in school mental health. The ideal teacher is an emotionally mature, secure person who can provide understanding while still representing the real demands of social and personal behavior. The teacher in today's society finds it hard to maintain self-esteem and pride in her work, he pointed out.

The behavioral science specialists' responsibility is not only to work closely and consistently with student teachers but to support those engaged in prophylactic group instruction, Nurnberger urged.

Where recognized neurotic or deviant interactions between teacher and student may develop, the social scientists are yet woefully ineffectual, he declared.

Only by cooperative effort can the highly complicated discriminations that determine success or failure in school mental health programs be delineated. Critical followup appraisal of student adjustments to life may develop a better understanding of what mental health really is and how to attain it, Nurnberger predicted.

Psychiatric Services Placed in Schools

Social work in schools thrives best when the psychiatric clinic is within the school, observed Dr. Oscar B. Markey, chief of psychiatry, Mount Sinai Hospital, and consulting psychiatrist in the public schools, Cleveland, Ohio.

This conclusion derives from the basic importance of the group approach to correction of maladjustment, and from the fact that the school offers the most important proving ground for the growth of personality after the pattern has been established in the child's home. Markey also felt that with a clinic in the school it is easier to stimulate a psychiatric attitude among teachers through workshops, case demonstrations, and treatment.

The responsibility of schools for the emotional and social education of the child is inescapable, he said, since emotional history is frequently associated with academic progress or failure, whether as a consequence of normal growth or morbid reactions. The academic experience itself is productive of certain emotional conflicts.

Markey suggested that professional school facilities should intensify their psychological, medical, audiovisual, and guidance services. He also suggested that if the psychiatric clinic cannot be located within the school, psychiatry and its allied disciplines should serve schools through community facilities or by means of psychiatric consultation.

Whatever efforts are undertaken, Markey concluded, the principal of the school remains the key figure, and the teacher is of first importance in the direct application of these efforts.

Voluntary Organizations Aid School Health

"Today's broadly conceived school health program cannot be isolated within the walls of the school and apart from the child's family and community life," asserted Dr. Ralph H. Boatman, director of health education, Tuberculosis Institute of Chicago and Cook County, Ill.

These walls are more easily breached, Boatman said, if the resources of voluntary organizations which are willing to provide staff time and funds to increase child health are properly utilized.

Boatman singled out the contributions of the National Congress of Parents and Teachers, and their local PTA units, to child health. They have sought, in cooperation with other voluntary organizations and government agencies, to make child health a family matter. They have recommended that school health activities be a continuation of earlier, familial experiences. If their suggestions are accepted, Boatman said, family physicians, parents, and teachers will plan sound health measures for the home, school, and community as a unit.

Efforts of the PTA in the past, Boatman pointed out, have resulted in improved community health through fluoridation of water, safety measures, and tuberculosis surveys.

Despite the PTA's willingness to cooperate on matters concerning child health, many school administrators and teachers have failed to appreciate the value of this resource, Boatman said.

Boatman described several instances where voluntary organizations, in cooperation with school and college officials, have provided information, professional knowledge, and skills to promote health. He also pointed out that these organizations have helped recruit health workers and have served as field training or observation centers for college and university students who are working on community health problems.

Voluntary organizations, he went on to say, have aided school health through research and the demonstration of new ideas. The nurse's affiliation with public schools had its beginnings in a voluntary organization's demonstration project, he said.

Voluntary organizations have also contributed to school health, Boatman added, by supporting desirable legislation, and by interpreting school programs, problems, and needs to the community.

How Schools Can Help The Disturbed Child

The school can help emotionally disturbed children in many ways, stated Dr. Harriett B. Randall, assistant medical director, Los Angeles City Board of Education. As essentials of school-provided help, she listed a healthful environment, intelligent intramural and extramural guidance, and stable teachers.

A punishing, rejecting teacher cannot help a distressed pupil or may not even be aware of his emotional distress, Randall asserted. The teacher must be able to detect the emotionally disturbed among children who are noisy and aggressive, or isolated and too conforming, or defiant and destructive. She must also recognize normal personality variations.

A teacher uncertain about a child's adjustment should have help from the school principal, parent, counselor, school nurse, doctor, and others skilled in child understanding, Randall stated.

Remedies

Once the disturbed child is recognized, a parent interview, a good physical examination, and psychometric tests are the first steps. These may indicate a remedy ranging from providing for a hot breakfast or lunch, a rest period, or new clothes, to obtaining glasses, a hearing aid, or treatment for anemia, *petit mal*, or parasites.

Randall cited the case conference, where all those working with a child pool their information and plan how the school can help him, as a productive technique.

The conference covers the child's school and health records; reports from the school nurse or doctor of examination findings, home visits, hospital and clinical findings, parent conferences, and classroom visits; from the counselor's psychological case study and psychometric tests; from the child welfare and attendance supervisor of home calls; from the teacher of observations and test results; and reports from the guidance clinic and school principal.

Arrangements to help the child adjust, Randall suggested, may be a short school day, remedial classes, a social adjustment transfer to give him a new start with new people, an appropriate transfer of a limited child to a school for the mentally retarded or for those with severe physical defects, or a short exclusion from school. However, all children cannot be helped in school; other pupils cannot be deprived because of extraordinary effort to aid the unadjusted child.

Study of Referrals

Randall discussed other procedures the Los Angeles school system uses. A difficult or urgent decision about a pupil is often referred by the local school to the health branch's central administrative office. Parents and teachers accept a central office deci-

sion more readily, and often the examiner is better prepared to aid the pupil.

A study reported by Randall of a random sample of 50 such special referrals during the past 5 years to the central office show that 30 of the students were boys and 20 were girls, and that their age spread was from 5 to 16 years. Fewest referrals were of 5-, 6-, and 8-year-olds (2 each), and the greatest were of 13-year-olds (8 referrals compared with 3 for 12-year-olds and 4 for 14-year-olds).

Only 19 children had parents currently living together; 17 lived with mothers; 2 with fathers; 1 with mother and stepfather; 1 in a foster home; 1 with mother, father unknown; and 1 with mother, father in a mental hospital. No data were available on the parents of eight children.

Thirty-three had marked or severe emotional instability; eight showed severe behavior disorders; and the others were psychotic or showed marked anxiety, apathy, or school phobia.

The study revealed that the most referrals were for aggressive behavior (20 boys, 8 girls); 8 (6 girls, 2 boys) were for withdrawal characteristics; and 14 for other types of behavior.

Exclusion from school for varying lengths of time was recommended for 36 of the children; 14 returned to school part time or on trial, but only 1 of them adjusted satisfactorily in the referring school.

Guidance Clinic

Randall described the school guidance clinic as another means of helping children. Los Angeles schools and the parent-teacher association jointly maintain a school guidance center and three branch clinics, headed by a chief psychiatrist and staffed with child psychiatrists, psychiatric social workers, and clinical psychologists.

The clinics treat children with school adjustment difficulties and offer diagnostic services and brief therapy. They work closely with the re-

ferral school as well as with the educational staff through inservice training. The guidance clinics are valuable in helping children to adjust, Randall stated.

Throughout the school system are people who help children with emotional problems. To assist a child, all staff members have a responsibility to work as a team, without duplication and lost effort. Prompt, efficient work will detect abnormal behavior early. Frequently aid is available within the school system, Randall declared.

Research Needed To End School Predicament

Research to determine what is presently being accomplished is school health's foremost need, declared Dr. Leona Baumgartner, commissioner of health, New York City Department of Health.

After recalling the history of APHA's school health section, she turned to future prospects in this field of service.

School health faces a peculiar predicament, according to Baumgartner. By 1975, the 5- to 17-year-olds will number 57 million, almost double the 1950 figure, if levels of fertility remain constant. Present shortages of all kinds of health personnel will be enormously magnified in the future. And there is now no real information as to what school health services actually accomplish.

These factors will make it ever more difficult to attract funds and workers, Baumgartner pointed out. Cost figures are difficult to determine, but more than \$58 million has been spent by schools in 40 States. School health personnel should be able to advise how to spend this sum, she said.

Research Needed

Baumgartner proposed greatly expanded research which can stand up to rigid scientific standards. This would include basic research on children's growth and development;

clinical research on the prevention of disease and disability and on early diagnosis and treatment for those afflicted; and broad scale, operational research of existing school health services.

She posed these questions: Are current methods in health education producing generations who live more healthfully than those in the past? What makes young people and their parents seek health?

What is the classroom's social and emotional climate? Can it be measured? Has it been examined closely enough?

Are medical and paramedical people finding and correcting a larger proportion of defects than 10 years ago? If so, have school health or other community health forces done this, and how has it been accomplished? Are there figures to compare one community's results with another's?

What type of studies of school activities has been most productive? What criteria have been developed to

test the effectiveness of school health programs? Are research workers being trained to do this job?

Cites Critique

Baumgartner cited a critique of school health services which analyzes past studies and suggests future investigations (*School Health Services: A Selective Review of Evaluative Studies*, by Bronson Price, Children's Bureau Document No. 362, January 1958).

She urged academic leaders, practitioners, and those who finance school health to give research top priority in the next decade.

School health personnel need to know if effort and scarce professional talent are being wasted. They can then abandon unfruitful procedures for practices which demonstrably improve the physical, social, and emotional health of school children.

"We dare not go on as we are now—asking for more and more of the same kind of service," Baumgartner declared.

Food and Diet . . .

Immune Milk May Give Protection to Humans

Human beings can acquire considerable passive immunity to disease by drinking milk from cows whose mammary glands have been stimulated to secrete specific antibodies.

Dr. Berry Campbell, associate professor of anatomy, and Dr. William E. Petersen, professor of dairy science, University of Minnesota, have demonstrated that adult humans can absorb a low percentage of antibodies from milk of very high titer.

Earlier experimenters failed to show that antibodies could be absorbed from milk because they had used milk of low titer and expected a high percentage of absorption, Campbell and Petersen said.

The remarkable ability of the cow's udder to produce antibodies was utilized to obtain immune milk. Vaccine injected directly into the teat canal, rather than intramuscularly or subcutaneously, resulted in milk with the highest antibody content.

Milk, like blood serum, contains a globulin fraction rich in specific antibodies. The mammary gland, with its large amount of lymphoid tissue, secretes milk's immune globulins. The spectrum of immunity in the milk corresponds to the cow's immunological history and serves as the early immunizing agent for the calf.

Immune milk is not a new subject, Campbell and Petersen pointed out. Sixty years ago Paul Ehrlich analyzed the transmission of protective antibodies through milk; his associate, Emil von Behring, believed that

immune milk could control human tuberculosis.

In the last 20 years it has been shown that milk antibodies are similar, if not identical, to serum antibodies. The authors demonstrated in 1950 that antibodies of colostrum and milk were manufactured in the mammary gland. This finding led them to try direct immunization of the gland to produce milk high enough in titer to be absorbed by human beings.

Absorption

Absorption of antibodies from immune milk was observed in both animals and human beings. Mice, tested for the milk globulin's protection against *Salmonella pullorum* infection, showed approximately 10 percent efficiency of absorption. Five milligrams by mouth equaled the protection of 500 micrograms given subcutaneously.

For this test, globulins were isolated from the milk of cows specifically immunized with this organism. Protective properties were quantitated by administration to experimentally infected mice. The prolonged life of the experimental animals over that of the controls indicated effective passive immunity. Fifty micrograms of immune globulins per mouse provided protection in massive experimental infection, and 5-microgram doses gave perceptible protection.

In human beings the authors also observed an uptake of immunity. For example, a man drank a liter of milk per day from a cow immunized with polyvalent streptococcus type A vaccine. The milk's titer was 1:1,000 dilution in a plate agglutination test. In 5 days the man's serum, previously negative, showed agglutinating antibodies, which increased to a plateau of 1:56 by the 19th day.

In other trials made with pollen antigens during the winter months, the skin tests of highly sensitive people changed from positive to negative after they drank milk containing blocking antibodies to ragweed pollinosis.

Some were kept free of all symp-

toms during the entire pollen season. In another experiment, 36 people received statistically significant protection over their controls by drinking a pint of immunized, powdered milk per day.

Implications

Pending large-scale field trials of immune milk, the authors have anticipated some of the implications.

A useful immune milk should be polyvalent, and in recent experiments they found that multiple immunization of cows was possible. One antigen did not interfere with another in milk from cows immunized with 21 strains of human enteric pathogens of *Salmonella*, *Shigella*, and *Escherichia*. Studies using a single packet of 11 antigens of bovine diseases had similar results. High titers to each species were obtained.

Injecting udders with antigens did not lower milk production in regular, high-grade commercial herds already immunized. Immunizing cows would, however, increase production costs. The manipulation involved requires a skill equal to the technique of artificial insemination, according to the authors.

They found that the temperatures necessary for pasteurization and for preparing powdered milk interfered little with antibody activity despite the heat lability of milk globulins. The heat needed to process canned milk, however, caused problems. Milk specifically immunized does not differ in taste, consistency, or chemical composition from ordinary milk.

Immune milk may lead to reevaluating the protein fraction of this food, they said. Breeding of cows and marketing and grading of milk have long concentrated on butterfat content and disregarded other constituents. The protein fraction will acquire a new importance if milk is used for protection against disease.

The potential of scientifically immunized milk has many implications for public health, Campbell and Petersen explained. Nutrition gains a new dimension beyond its present goal of maintaining energy balance

and health. And understanding how mammals protect their young from disease through milkborne antibodies may yield new techniques to battle illness.

Food Additives Pose Continuing Problems

Chemicals and antibiotics in food today confront those administering food and drug laws with many problems. Robert S. Roe, director of the Bureau of Biological and Physical Sciences, Food and Drug Administration, pointed out some current problems and showed how present legislation deals with them.

In the last 15 years science and technology have created new organic compounds, new drugs, new manufacturing processes, and new packaging. And the stabilizers, preservatives, antioxidants, tenderizers, emulsifiers, sweeteners, colors, flavorings, growth promoters, and residues of fungicides, insecticides, defoliants, and herbicides that find their way into the food supply seem limitless, Roe declared.

The Pesticide Amendment to the Food, Drug, and Cosmetic Act, passed 3 years ago, regulates one type of food additive. It provides for establishing safe tolerances for residues of pesticides in raw agricultural products. Administering the law has revealed many difficulties. But the statute is workable and has resulted in several hundred tolerances on various products, stated Roe.

Colors and Poisons

Coal-tar color additives are governed by special provisions of the law. The statute authorizes the listing of coal-tar colors that are harmless and suitable for use in food and for certification of batches of such colors. Under this provision 18 colors were listed as harmless and suitable for use.

However, the application of newer techniques in pharmacology and more complete information on

the chemistry of these dyes have caused 3 colors to be delisted in 1956, and delisting procedures for 4 others are under way. An amendment to the law, recently introduced in Congress, would relax the present harmlessness rule and replace it with authorization to establish safe tolerances for coal-tar colors.

The Food, Drug, and Cosmetic Act also prohibits adding any poisonous or deleterious substance to food unless the addition is required in production or cannot be avoided in good manufacturing practice. If the addition is necessary or unavoidable, then safe tolerances may be established.

But this provision fails on two counts to solve the problems of chemical additives, Roe said. First, the poisonous or deleterious properties of many substances may not be known, and to prevent their use, the Government must be able to show affirmatively that the additive in question is poisonous.

Second, some additives, while not necessary, may be desirable to improve nutritive values, preserve color or flavor, or serve purposes useful to the consumer. The law, however, permits no additive unless it is necessary.

Misuse of antibiotics in treating animals may also affect food derived from these animals. For example, penicillin used to treat cows for mastitis has appeared in their milk. Even small amounts of penicillin may cause serious reactions in persons sensitive to the drug. Changes in the antibiotic regulations, relative to certification of mastitis preparations, have been instituted to correct this.

Antibiotics, when used as food preservatives, are in the category of pesticides. While tolerances have been established for residues of some antibiotics used to treat raw poultry, we think that generally antibiotics have no place in food as consumed, said Roe.

Antibiotics, estrogenic hormones, arsenicals, and other chemicals that affect growth or fattening when added to stock or poultry feed may

find their way into food. When used as growth-producing or fattening agents they are classified as drugs.

Under the law a new drug cannot be distributed unless it is the subject of an effective new-drug application, submitted by the promoter along with adequate evidence of the substance's safety. The Food and Drug Administration has held that evidence of safety in drugs intended for animal use must include proof that there are no residues in food derived from the treated animals, Roe stated.

Unsolved Problems

The problems posed by chemical additives are of great public health significance. They are particularly complex because the question of safety usually does not involve acute toxicity, but the more subtle and difficult-to-appraise chronic toxicity.

Consideration of the use of additives Roe said, involves such difficult questions as: What is the effect of regularly consuming a quantity of a chemical over periods of years? Will relatively innocuous additives adversely affect a food's nutritive values? What are the possibilities that mixtures of additives at safe levels will have a potentiating effect on toxicity? How can the chronic effect of ingesting additive residues be detected and measured in human beings?

Method Will Measure Attitudes Toward Food

Increasing a patient's self-esteem and minimizing authoritarian control over him can reduce malnutrition associated with emotional disturbance, said Dr. Franklin C. Shontz, psychologist, Highland View Hospital, Cleveland, Ohio.

When eating problems are the cause, or a contributing cause, of physical malfunction, treatment is especially difficult, from a psychological point of view. But when unhealthy eating behavior is a superimposition upon a disease unrelated

to dietary insufficiencies, treatment is possible, he said.

In this latter case, problems in eating stem from an intense emotional reaction to being ill and hospitalized. Fear, hostility, and a sense of self-disintegration are not unlikely reactions. In addition, Shontz observed, a patient may have a life-long history of borderline nutritional adjustment.

The hospital setting, Shontz said, is particularly trying. For the hospitalized patient, there is not only the necessary physical loss to face, but there may be an even greater loss: the loss of privacy; the loss of self—the possible identification as being first and foremost a disease. The whole situation is only made more difficult by the fact that one no longer has his choice of what he is to eat; one no longer picks his dining partners; one no longer decides when and where he will eat.

Under these conditions, the patient may adjust poorly to any dietary schedule. But up to now, Shontz said, there have been no means of measuring, no controlled research on, the adequacy or inadequacy of any specific regimen.

To offset this situation, Shontz offered a method by which environmental influences on eating habits could be determined.

First, he said, one must formulate a criterion of nutritional adjustment. This criterion should be able to measure (a) the adequacy of the patient's diet, (b) his attitudes toward food, (c) the manner in which food is served, and (d) the total hospital situation. The criterion would provide, Shontz said, "an index of nutritional adjustment as well as a yardstick by which changes in food acceptance may be evaluated."

Second, patients should be allowed at least limited choice in what, when, and with whom they eat. At meal times, he cautioned, "they should be fed promptly and regularly, and by people they genuinely like."

Third, after the patient has been permitted a limited choice in these matters, the choices should be curtailed for a while one by one, and

then reinstated. Each change that is really important to the patient would be reflected in the measurements established by the criterion of nutritional adjustment.

Experimentation along these lines, Shontz said, will result in better patient care and will increase our knowledge of the psychological factors in eating.

Dieting Is Inadequate For Obese People

Reducing is not a cure for obesity, paradoxically asserted Dr. Hilde Bruch, associate clinical professor of psychiatry, Columbia University. And she warned against efforts that treat only obesity and not the person.

Reducing should follow upon improvement in the obese person's total adjustment. "The ability to reduce," she said, "is only a confirmation that such improvement has taken place."

We too often look upon overweight as a deviation from a norm, she said. Decriing this attitude, she observed that individual differences are far more important in obese people than statistical similarities.

Bruch pointed out that there are many different types of obesity. Weight excess in some adolescents, for example, may simply be a function of rapid growth and development, or it may be "normal" according to their constitutional makeup. For others, overweight may be caused by physiological pathology or emotional maladjustment.

When obesity is a function of psychological maladjustment, it should be considered as symptomatic of some underlying disturbance and treated accordingly. But treatment, she said, should not be instituted on the basis of weight alone.

Condemning social derogation of obesity, Bruch called for a reeducation of the public which has humiliated, rejected, and isolated the fat person. Untoward criticism of the obese person, solely because of his excess weight, may precipitate emotional disturbances which in turn

may lead to greater obesity and perhaps to severe mental illness.

Synthetic Food Enrichment Need of Hungry Lands

If the world's population ever seriously taxes total food supply, the only way to make the cheapest foods protective is by chemical synthesis, according to Dr. Robert R. Williams of the Williams-Waterman Fund for the Combat of Dietary Diseases, Research Corporation, New York City. "It requires about seven times as much land to produce a million calories of meat or milk as it does to produce a million calories of cereals," he said.

Williams first forecast the world pattern of adoption of current types of food enrichment. The practice of enriching fats with vitamin A, if extended to cooking fats by the use of suitable antioxidants, he prophesied, would take the lead over all other types, since fats are used in some form by all peoples. There is a deficiency of this vitamin in the staple foods of the masses in developing countries, and the vitamin is cheap. Changing dietary patterns is slow, he said, and impossible if the shift in crops is uneconomic.

The practice of enriching cereals, which supply 80 to 90 percent of the calories for the majority of the world's population, is the most widespread at present, largely to offset the tendency to mill wheat, rice, and sometimes barley to whiteness. Williams concedes that such milling may someday be outlawed or abandoned, especially if the difficulty of conserving undermilled products is surmounted. However, present trends are not in that direction.

Voluntary rice enrichment in the Philippines, as in other developing countries, is inhibited by the competitive disadvantage of the added expense, but Williams feels the mandatory enforcement of that practice in the Philippines, with a conspicuous fall in the death rate, will pave the way for its success in most of rice-eating Southeast Asia.

Vitamin D fortification of milk Williams expects to be confined to areas of colder climate, and the addition of iodine to salt, to goiterous areas.

The Economic Hurdle

As for chemical synthesis of the total food supply, Williams pointed out that the major food components—carbohydrates, fats, and proteins—are produced vastly cheaper by the farmer than by the industrial producer. Under noncompetitive conditions, glucose as food has been made from woodpulp, and fats from petroleum. He also mentioned experiments combining sugarcane, an abundant crop, with blackstrap molasses and synthetic urea for the carbohydrate and protein needs of cattle.

Williams believes that for some generations to come the major supply of food will come from the farm. He questioned, however, whether all the advances in farming for another hundred years will meet the needs of a population growing at an accelerated rate.

The lack of good protein is the key challenge for ill-nourished peoples, said Williams, as evidenced by kwashiorkor among children where animal protein is low. Since animal proteins are superior to cereal proteins in three amino acids, logically by supplementing cereals with these acids in proper proportions, the deficiency would be repaired. But to produce required amounts would be uneconomic at present.

Williams' solution lies in reducing costs through large volume production. Pointing to the fall in prices of thiamine and riboflavin from \$1 a gram to 4 cents, he urged that producers be encouraged to make and market synthetic organic chemicals.

Atherosclerosis Research Seen Changing Diet

Stressing the uncertainty of the role of diet in atherosclerosis, Dr. Juanita A. Eagles, assistant research professor at the University of Pittsburgh Graduate School of Public

Health, cautioned health educators against generalizations on the subject.

At the same time, she does see the possibility of sweeping changes in the adult diet, once data from current research become definitive. Certain findings relate the diet's total calories, fat, and animal protein content with atherosclerosis and hypercholesterolemia, she said, pointing out that the "well-fed American is now said to be consuming a diet of 12 percent protein, 50 percent fat, and 38 percent carbohydrates."

Presently, the nutritionist interprets the physician's dietary directions to the patient, attempts to overcome emotional and cultural objections to the change, and studies the effect of stressful events on adherence to the diet. But as a result of research, she said, nutritionists may have the task of changing diet habits of the hypothetical "coronary-prone" United States population estimated at 50 million.

As for atherosclerosis, Eagles advised teaching dietary habits to the young in order to influence the largest number of persons and to emphasize preventive values in health practices. Besides, she added, it is easier to develop food habits in young people than to change fixed habits in the mature.

Food Enrichment Spurred In Near and Far East

A review of nutritional studies seeking ways to enrich food in several countries of the Near and Far East was presented by Dr. Arnold E. Schaefer, executive director of the Interdepartmental Committee on Nutrition for National Defense, National Institutes of Health, Public Health Service.

On official requests from Iran, Pakistan, the Philippines, Turkey, Korea, and Libya, the surveys were launched by the interdepartmental committee in January 1956, and, as part of the Mutual Defense Assist-

ance Program, were directed primarily toward the armed forces of the host country. In addition to defining nutritional needs through biochemical and physical tests and food studies, the program aimed at training personnel in evaluation techniques and providing basic equipment for nutrition laboratories.

Schaefer reported that in general the major nutrition deficiencies were of riboflavin, thiamine, and vitamins C and A. In recommending food enrichment methods, he said, the committee kept in mind possible variations in nutrition needs within each country, as well as the value of keeping in harmony with local diet patterns and nutrition concepts.

In Korea, the committee recommended that enrichment of white flour supplied by the United States be raised to 3 mg. from 1.2 mg. of supplemental riboflavin per pound.

As a result of the survey findings, the Pakistanis are now conducting a study on effects of iodine intake on goiter in adolescents, and on related production and distribution questions.

In Turkey, Schaefer said, flour enrichment with riboflavin was being considered. The committee recommended increased fortification of margarine with vitamin A as well as control measures to insure the new level. Also suggested was a more even distribution of leafy vegetables, citrus fruits, and of the native "rose cake," a rich source of vitamin C.

In the Philippines, the committee recommended that the rice enrichment successful in Bataan against beriberi be extended throughout the islands, said Schaefer.

For the Republic of China in Taiwan, the committee advised that a rice enrichment pre-mix plant be set up and that pre-mix feeding machines be installed in mills supplying the Army. Surplus plant capacity would produce enriched rice for schools and other official institutions, he said. To avoid delay in raising enrichment levels, the alternative use of an enrichment wafer

was recommended and initiated, with the advantages of standardized recipe and equipment, rapid operation, low cost, and uniform rice color.

Among sidelights of the surveys, Schaefer recalled that in Libya, despite inadequate intake of calories, riboflavin, thiamine, and vitamins C and A, classical signs of nutritional deficiency appeared in few men examined. Such findings, he said, underline the need for study of body adaptation to suboptimal intake of multiple nutrients.

He remarked also on the value of *kimchi*, a preserved mixture of radishes and Chinese cabbage noted in the surveys, which is an excellent source of vitamins C and A for winter. Food fortification may well use fermented products someday, he said, citing also the enrichment of *miso*, a fermented soybean product of Japan, and Japanese experiments on a high riboflavin producing yeast for fermenting *miso*.

Psychiatrist Prescribes Look Into Diet Changes

Any public health dietary prescription must take into account symbolic and emotional meanings of food and eating, according to Dr. Walter W. Hamburger, associate professor of psychiatry, University of Rochester School of Medicine and Dentistry.

Food preferences as well as eating habits are emotionally invested with these personal meanings. Each individual's life experience determines them. The child's emotional relationship to his mother and other early childhood experiences in the family are potent factors in setting eating patterns, Hamburger maintained. The cultural pattern in which people live plays a large part in establishing non-nutritional meanings to food and eating.

Some people are aware of the reasons for their food likes and dislikes; others are not. Some of these associations and symbolic meanings have been learned from clinical psy-

chiatric and psychoanalytic experience, Hamburger said. Some general principles have been derived, but research is needed in many specific areas, such as decreased or altered fat intake.

The motivation for dietary changes and possible emotional complications arising from attempts to make major changes in the diet will contribute to the efficiency of any dietary public health program. There is evidence that emotionally stable individuals can more easily modify their diets than can those who are not stable. This observation has been made in response to the question of reducing diets for the obese.

Similarly, the incidence of emotional complications ensuing from major dietary changes would be greater in the emotionally unstable. This is because certain individuals utilize specific eating patterns and even specific foods to satisfy their emotional as well as their nutritional needs. For such individuals, attempted alterations of eating patterns for nutritional or public health program reasons may lead to emotional complications. Hamburger feels this is less likely when food substitution is recommended (unsaturated for saturated fats) than when total food restriction is advised (low-calory reducing diets).

temperature was above the median for those months, first admission rates increased. Admission rates were 1.658 per 1,000 for July and 1.519 per 1,000 for August, compared with 1.276 and 1.206, respectively, in those years when the mean temperature was below the median. Total admission rate, when the weather was hot in June, July, and August, was 1.524, compared with 1.295 when the weather was cool ($\chi^2=10.02$; $P<.001$). On the basis of mean temperature, July's difference is three times as great as the difference between the first and third quarters of all the years under investigation.

The accompanying table compares first and third quarters, and months within those quarters, for significant variations.

The significance of their findings for public health workers, they believe, lies in the fact that environmental rather than inherited factors may play a larger role in the formation of the individual than heretofore believed. Public health workers, the report recommends, by paying greater heed to dietary control, particularly in hot months, can take measures to prevent mental deficiency.

Mental Health . . .

Climate and Diet Cause Mental Deficiency

Inadequate diet in early pregnancy during hot summer months may have an adverse effect on child development, according to Dr. Hilda Knobloch, director of the child development clinic and associate professor of pediatrics, and Dr. Benjamin Pasamanick, director of psychiatric research and professor of psychiatry, both of the Ohio State University College of Medicine, Columbus.

Since damage to the cerebral cortex during its formation in the third month after conception could affect intellectual functioning, the authors originally sought to test the postulate that the prevalence of viral infections during winter months would result in a greater incidence of mental deficiency among infants conceived in those months than at any other time.

Their findings, however, introduced another hypothesis, because the first trimester of mentally deficient children occurred more frequently during the summer than

winter. The cause of mental deficiency, therefore, Knobloch and Pasamanick suggested, may be related to the tendency of expectant mothers to reduce their food intake, especially proteins, to dangerously low levels during hot weather.

This conclusion emerged from the study of the records of 5,855 admissions of mentally defective children to the Columbus State School between 1913 and 1948.

In these records they found, for example, that when the eighth to twelfth week of pregnancy occurred in July or August, and the mean

Problems in Measuring Patient Changes Outlined

Admission rates for mental deficiency, by season of birth, Columbus State School, 1913-48¹

Season	Number of births ²	Number of admissions	Rate per 1,000
February ³	339, 704	512	1. 507
August ³	377, 085	489	1. 297
January, February, March ⁴	1, 064, 183	1, 535	1. 442
July, August, September ⁴	1, 112, 933	1, 467	1. 318

¹ Excluding 1946. ² Number of births in each month supplied by the Ohio State Health Department. ³ C.R.=2.3; $P<.02$. ⁴ C.R.=2.4; $P<.02$.

the United States decreased in fiscal year 1955-56 from 559,420 to 552,005, the second decrease ever noted in these hospitals.

Moreover, the observed number of resident patients was 21,855 less than the 573,890 patients expected on the basis of the 1945-55 trend. This deviation from trend was by far the greatest that occurred in the period under study.

These are some of the facts uncovered by Dr. Morton Kramer and Earl S. Pollack of the Biometrics Branch of the National Institute of Mental Health, Public Health Service.

Since the decrease occurred at a time when tranquilizers were being used extensively, Kramer and Pollack discussed the problems involved in assessing the effect of tranquilizers as well as other therapeutic procedures on patient movement in hospitals. Their analysis emphasized the inadequacy of crude movement data in making these assessments, and they suggested a data collection method that would yield more sensitive indexes.

Expected and Observed Values

In comparing observed values in 1956 with those expected on the basis of the 1945-55 trend in the public mental hospital systems of the 48 States, Kramer and Pollack found:

- Admissions were higher than expected in 24 and lower in 24.
- Net releases were higher than expected in 33 and lower in 15.
- Deaths were higher than expected in 42 and lower in 6.

Population Changes

Gross changes in a mental hospital resident population, Kramer and Pollack pointed out, are a result of additions to and removals from a baseline population. They show, in the accompanying chart, how this addition and subtraction takes place.

The chart portrays a hypothetical hospital with a resident population of 1,000 at the beginning of a year. During the following 12 months, 303 persons are added (243 admissions

and 60 returns from extramural care), and 276 are removed (187 releases and 89 deaths). Since additions exceed removals by 27, the resident population at the beginning of the next year is 1,027.

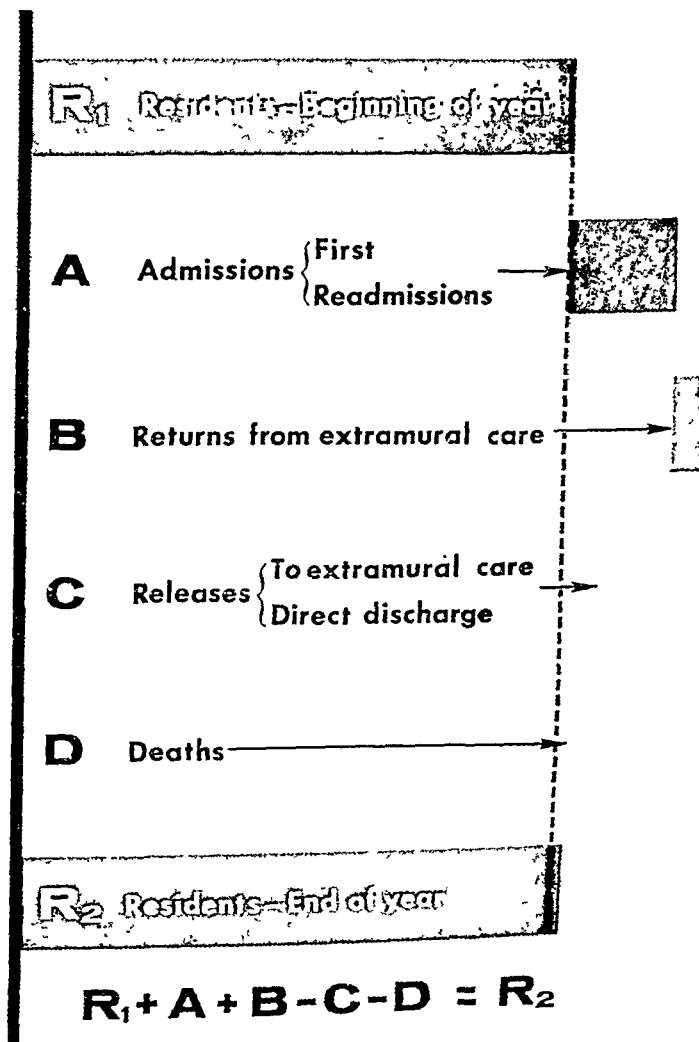

National data are available, the authors added, on all movement items except B and C in the chart. It is possible, they pointed out, to determine C-B, which is the net number of patients released to the community in any one year.

The authors emphasized that changes in size of resident population between two points in time is a

function of three variables—admissions, net releases, and deaths. They stated, "If we are to understand the factors that account for the rise and fall of mental hospital populations, we must undertake studies that relate variations in admissions, net releases, and deaths not only to hospital factors but also to extra-hospital factors which can affect these variables."

To provide some of the information needed for proper analysis, Kramer and Pollack suggested the compilation of (a) resident patient cards at the start of each year containing

Gross changes in a mental hospital resident population.

basic data on each patient, such as age, sex, diagnosis, duration of hospital stay, and any other desirable data, and (b) patient movement cards recording significant movements in or out of hospitals during a year. These cards should contain the same information on each patient as the resident patient cards.

The introduction of new treatment methods and new psychiatric facilities affects the use of facilities and treatment in the reduction of disabilities from mental disorders. Measuring these effects, the report concludes, is an epidemiological problem.

To quantify the impact on the mental hospital of tranquilizing drugs and such other therapies and programs as may be developed in the future requires revision of existing statistical systems. But equally important, the authors went on to say, is the development of programs which will coordinate data on utilization of all community treatment facilities so that the mental hospital's role can be studied in relation to that played by these other community facilities in the treatment and rehabilitation of the mentally ill.

Interview Experience Eases Relationships

Public health workers develop greater self-confidence as a result of 5-day interpersonal relations institutes, according to Hyman M. Forstner and Dr. Joseph J. Downing, New York State Department of Mental Hygiene, and Dorine J. Loso, Public Health Service, Denver, Colo.

The authors described and evaluated 4 institutes of 11 conducted by the departments of health and mental hygiene in New York State since 1950.

Description

The institutes were normally composed of 25 voluntary participants meeting in a relatively isolated community where beneficiaries of health services were available for interview-

ing. Several members from each of several health units were invited to participate because it was felt that the effect of the experience would be greater and more lasting than if only one attended.

Demonstration interviews were held in the mornings. In these, the participants observed a psychiatrist and his subject through one-way vision mirrors and listened through headphones to their conversation. The psychiatrist who conducted the interview informed his subject that public health people were listening; but not that they were looking.

The participants' attitudes toward these interviews were later analyzed, and it was found that they had at first identified themselves with the client, but gradually shifted identification to the psychiatrist. By the fourth day, the shift was complete. This experience brought into the open the reluctance of participants to ask people about their life situations, a reluctance indicative of a general resistance to self-appraisal.

This resistance, on the other hand, produced tensions upon which the success of the institute depended. The most successful institutes, the report states, were those where initial tensions were high and gradually came to their lowest point on the last day.

In the afternoon, participants conducted interviews, each on his own unless he wished to include others. A psychiatrist maintained control over the proceedings. Morning and afternoon interviews were followed by discussions.

Evaluation

The participants found the institutes valuable. The report states, "They tell us their approach to fellow workers and to clients is easier, more pleasant, and more rewarding."

Objective psychological tests, administered by the institute's staff when it was over, revealed that participants were less dogmatic and less rigid in their behavior. At the same time, there was a loss of interpersonal acuity and an increased ac-

quiescence to authority. These latter tendencies disappeared within 6 months, and a greater self-assertiveness, expressed through self-confident behavior, was found, the authors reported.

Psychiatrist's Time Used Economically

"The child psychiatrist in a public agency can make his greatest contribution to the mental health of his community by functioning as a diagnostic consultant . . . and by delegating appropriate therapeutic tasks to ancillary personnel."

This approach will increase the number of patients the psychiatrist will be able to see, according to Dr. Leon Eisenberg, assistant professor of psychiatry and pediatrics at the Johns Hopkins University and Hospital, Baltimore.

Eisenberg submitted results obtained from a special diagnostic clinic set up to help 48 foster children who were emotionally disturbed.

Treatment began with a diagnostic conference to determine type and severity of disturbance and suitable placement for the children. After these decisions, case workers from the welfare department were given the responsibility "to develop a sustaining relationship with the child, to interpret clinic findings to foster parents, schools, and court, and to secure group activities."

Among other therapeutic measures were the assignment of Big Brothers, speech correction, and the substitution of new peer activities for the company the children had been keeping.

After an average interval of 1 year, the 48 children were resurveyed. Information was obtained on 44 of them. Of these, excluding 6 who were institutionalized, 27 (71 percent) showed improvement.

Since 11 of the 38 children actively treated did not receive the recommended treatment, for one reason or another, a comparison of this

group with those who did receive recommended treatment was possible, and the advantage of psychiatric consultation, Eisenberg pointed out, could be determined. Where the treatment plan was not followed, only 3 showed improvement (27 percent); where the treatment plan was followed, 24 showed improvement (89 percent).

These figures indicate, Eisenberg concluded, that a good consultation service for foster care children results in substantial improvement.

During treatment, several factors were uncovered relating to staff morale and the promotion of good consultation services. Agency workers, Eisenberg said, should be included in discussions and preparations of social histories without interposing psychiatric social workers between them and the clinic team. He also suggested that test analyses and clinical opinions should be expressed in clear terms, avoiding jargon. Remarks not relating to actual behavior may only confuse the agency worker or suggest difficulties beyond the scope of her abilities.

Epidemiological Method Measures Child Behavior

An epidemiological method for measuring behavior in children was reported by Dr. Remy Lapouse and Dr. Mary A. Monk, associates in preventive medicine and public health, University of Buffalo School of Medicine. Dr. Lapouse is also an associate in psychiatry.

Their report covered a pilot study of 482 children between the ages of 6 and 12. The sample used was representative of the population of Buffalo. The subjects thus were children "who are not likely to be picked out of the community for psychiatric examination and therefore have little chance of contributing to the statistics of symptoms."

Because of the general difficulty in differentiating reliably between normal and abnormal behavior,

Lapouse and Monk preferred avoiding definitions of pathological behavior. They developed instead "a method for measuring the prevalence and interrelations of certain behavior characteristics of children." The ultimate aim, they said, is to gain accurate knowledge of the prevailing forms of behavior of children, their frequency and severity, and their correlation with the adjustment and function of each child so that deviations from the usual pattern may be more objectively evaluated and, consequently, an effective method for identifying the psychiatrically sick child in the community may be evolved.

Mothers Interviewed

Mothers were used as the primary source of information on child behavior. Interviews, 1½ hours long, were designed to elicit information on the child as well as on certain family and household characteristics. Interviews were obtained with 94 percent of the sample. Information was sought on a wide range of child behavior including social and intellectual behavior, body control and coordination, habits, and physical and mental factors that modify or limit behavior. In a check on the validity of the mothers' responses, a new sample of 193 mothers with one child each was selected for interview. Mother and child were interviewed separately but simultaneously. Both groups were asked the same questions, and the responses were compared.

Since the pilot study was undertaken primarily to develop a valid and reliable epidemiological method

for the investigation of behavior in children, and since an analysis of only a small part of the data collected is reported, the actual findings are tentative, the authors said.

Responses Compared

With regard to the validity of the mothers' responses, Lapouse and Monk found that the mother's agreement with the child is highest when the behavior is concrete, objectively observable, or has a high nuisance value as measured by social standards. Thus mothers could be relied upon to agree more consistently with their child when reporting bed wetting, thumbsucking, stuttering, and so on.

There was far less agreement between mother and child on subjective behavior such as nightmares, amount of food eaten, restlessness, overactivity, or fears and worries. Indeed, 40 percent of the mothers, they found, underestimated the fears and worries of their children.

In the partial analysis of their data Lapouse and Monk observed that for a representative sample of children mothers reported a high prevalence of several characteristics commonly thought of as pathological. The authors raised questions as to the interpretation of this finding: whether it means that a large number of children are psychiatrically ill, or whether these characteristics occur in essentially normal children. It was suggested that the answer may lie in an evaluation of the children's capacity to function effectively in their environment. The authors plan to report on this aspect of their investigation in the future.

Water, Wastes, and Safety . . .

Public Health Hazards Created by Radiation

Developing sound criteria of maximum exposure of individuals and the general population to radiation

is at once vitally important and tremendously difficult, averred Roy J. Morton, associate leader, Waste Disposal Research and Engineering Section, Oak Ridge National Laboratory.

Morton reviewed the need for integrating radiation protection with public health practice and gave examples of the expanding use of nuclear energy. In addition, he discussed some of the aspects of control, specifically preventive control, of environmental exposure to radiation.

Need for Control

In the past, Morton pointed out, some people were seriously injured or killed by radiation from X-ray machines or other sources of radiation, and protective measures were left to specialists. Radiation control was an individual concern.

Today, ionizing radiation has become a community burden. Not only is there background radiation, but there is an accumulation of public dosage from exposure to radiation used in medicine, dentistry, industry, research, and weapons development. These sources of radiation are in addition to nuclear energy operations for which comprehensive radiation control measures have been provided to protect workers and surrounding communities.

"The basic public health responsibility is to maintain all radiation exposures within the generally accepted limits without in any way discouraging the utilization of radiation sources to their maximum advantage," Morton said.

Radiological Health

"Radiological health," Morton explained, "is generally accepted as the inclusive term for all public aspects of ionizing radiation in relation either to the prevention of injury to people or the uses of radiation and radioactive substances to improve public health. The primary goal of radiological public health is to avoid all unnecessary radiation exposure of human beings. It is impossible, of course, to limit exposure to zero, but exposures above zero should be regarded as undesirable and condoned only when the gain from such exposure warrants the risk. The minimum public health responsibility is to be sure that accepted

standards of maximum permissible dosages are observed including recommended limits for the total population which should be set at levels well below those that are acceptable for persons occupationally exposed to radiation."

Eventually, Morton believes, radiation control procedures will be integrated with established public health practice and will be handled in much the same way as other public health activities.

Health Problems

The use of X-rays, Morton said, constitutes the most urgent and widespread source of critical public radiation exposure. At the present, some of the aims, Morton indicated, are "to improve X-ray machines, installations, and techniques so as to minimize the radiation exposure of operators and patients." It has been demonstrated that familiar techniques can reduce individual diagnostic X-ray exposures more than 95 percent, and completely shield critical areas of the body, with no loss in utility of the X-ray picture.

The use of radionuclides in research constitutes a relatively minor source of exposure. The list of radionuclides, published by the Oak Ridge National Laboratory, now includes about 85 processed elements, with a half-life varying respectively from less than a day to millions of years.

Radionuclides are frequently employed as tracers, Morton said. Small quantities of short-lived radionuclides suffice for most tracer applications because of their sensitivity to counting methods, and hazards can be avoided by using small amounts of quickly decaying radioactive material. On the other hand, radionuclides as high level radiation sources may involve large amounts of radioactive materials and high radiation fields. The techniques of elaborate shielding and other safeguards for high level radiation uses have already been developed and evaluated, Morton said.

The greatest prospective source of radiation is the nuclear high-energy

power reactor, he said, but also noted approximately 25 low energy installations designed for use in research and training. The number of reactors is increasing rapidly. The source of radiation of most concern to the public is the fission product rather than the process of fission itself.

Unless fission is replaced by a fusion process, which creates no radioactive products, radioactive wastes will be one of the major concerns of radiological public health, Morton pointed out. By the year 2000, there should be "an accumulated volume of high-activity reactor fuel process wastes of the order of 550 million gallons and with total accumulated radioactivity of many billions of curies."

Industrial Uses Grow

Citing information from the Atomic Energy Commission, Morton indicated the rapid expansion of the Government's nuclear energy operations:

- Government investment in atomic energy plants and equipment increased from \$2 billion in 1951 to \$6.5 billion by July 1956.

- In fiscal year 1956, the Commission spent \$177 million on reactor development and related activities, nearly \$52 million of which was for civilian experimental power reactors.

- The AEC research and development program, exclusive of support to military projects, costs about \$250 million each year.

- In fiscal year 1956, \$18 million went to private contractors for some 800 research projects.

The 22d semiannual report of the AEC for January-June 1957, Morton pointed out, lists 267 reactor facilities that have been planned, or built, or are in the process of being built. Five full-scale civilian power reactors are being built and 17 are in the planning stage. Of the 22 chosen locations for these reactors, 16 are distributed in 10 States, Puerto Rico, and Alaska; 1 is in New England, 2 in the Ohio Valley, 1 on shipboard, and 2 are unspecified.

After advising against exaggerating and overpublicizing the promise and hazards of nuclear energy, Morton concluded that "the logical objective is to deal with the radiological health and environmental control problems as they now exist, to study and learn more about the fundamental factors involved, and to develop rational methods of control that are as conservative and adaptable as possible."

Clean Water Law Aids 700 Communities

About 700 communities were offered Federal aid and 600 others applied for grants during the first year the Federal Water Pollution Control Act of 1956 has been in effect.

Robert R. Harris, chief, Construction Grants Section, Water Supply and Water Pollution Control Program, Public Health Service, discussed this and other consequences of the legislation.

New facilities and improvements to existing sewage works costing more than \$250 million have already been aided by this act. Federal contributions for the first year reached \$56,237,000; a ratio of 4 local dollars to each Federal dollar, Harris stated. The law limits the Federal share of grants to \$250,000 or 30 percent of the cost, whichever is less.

He noted that the \$95 million appropriated for grants during the first 2 years is far short of the amount communities have already requested.

The Federal grants have made their biggest impact upon small communities, Harris stated. The first 127 Federally aided sewage treatment plants in 7 midwestern States will reduce pollution from municipal sewers in 1,700 miles of streams to satisfactory levels. Ninety percent of the communities these plants serve have populations under 25,000.

The legislation provides that half the grant funds must aid communities of 125,000 or less; 84 percent of the funds already allotted have gone to communities in this category.

State Participation

The most significant feature of the act, Harris said, is the reaffirmation by Congress of the States' primary right and responsibility to prevent and control water pollution. Federal activities primarily support and supplement the efforts of State and local agencies.

Municipalities wishing Federal aid must first apply to their State water pollution control agency. The State approves the application and certifies that the proposals it contains have priority over others in the State.

The act specifies that the priority must be based on financial as well as water pollution control needs. A Federal grant offer is made subject to the terms and conditions specified by the State and the Public Health Service.

Financing methods the communities have used depend upon their fiscal resources and State laws. General obligation bonds, certificates, or warrants payable from ad valorem taxes of a municipality are most popular. But revenue bonds and certificates and special assessment bonds have also been used. Often a community raises funds from several sources such as unencumbered cash, proceeds from several types of bonds, Federal loans, and grant moneys from State and Federal governments.

Several State governments now offer assistance to communities. Partly stimulated by the Federal Water Pollution Control Act, the Maine, Maryland, and Vermont legislatures in 1957 established supplementary grant programs. New Mexico voted special assistance to rural unincorporated areas, and Ohio created an emergency Village Capital Improvement Rotary Fund to make advances for planning.

New York, Pennsylvania, California, and Oregon already had some form of State assistance.

Law's Impact

The act contains broad definitions: treatment works include interceptor

and outfall sewers, pumping, power, and other equipment, as well as extensions, improvements, remodeling, additions, and alterations of existing treatment works; construction includes preliminary planning, necessary engineering, architectural, legal, and fiscal investigations and services, preparation of designs, specifications, and plans, and inspection and supervision of the construction.

As a result, Harris said, many treatment works not otherwise possible are being built through combined Federal, States', and local governments' efforts.

The Federal grants already offered will aid sewage treatment plants serving 10,500,000 people and an estimated 14,000,000 in the future. Harris pointed out, however, that some 9,000 communities need new or improved facilities.

The Nation's annual per capita expenditure for construction of municipal sewage treatment works is about \$2.42, based on the 1950-54 average. Even if this rate is maintained until 1985, the population equivalent of sewage still delivered to streams then will be 25 million higher than it is today, Harris stated.

Bonds Finance County Water, Sewage Plants

Methods used to finance the 97 sewage treatment plants and 150 water plants in Harris County, Tex., were described by Roger Moehلمان, sanitary engineer, Harris County Health Unit.

Outside Houston, with its 900,000 population, 200,000 people live in small cities and unincorporated areas where suburban development has mushroomed since 1915. In these fringe areas 15,000 lots were subdivided in 1955, 13,000 in 1956. Water supply and sewage disposal facilities were lacking, and most suburban developers had to provide these services for their own subdivisions.

Septic tanks and shallow wells

WATER AND SEWAGE

were eliminated in most developments by policies of the Federal Housing Administration, Veterans Administration, and loan companies. The agencies did not insure or the companies lend money for purchasing homes unless the Harris County Health Unit approved sewerage and water systems. The unit also inspected and approved plants built according to plans approved by the State health department. Sewage disposal systems are required to have a complete treatment plant; often effluents flow into dry ditches or streams with inadequate flow.

Financing Methods

Water and sewerage systems in Harris County were financed through city systems with city bonds, water control and improvement districts, fresh water supply districts, and private capital, Moehlman stated.

Under Texas legislation a State board of water engineers can create a water control and improvement district after hearings called upon petition from those living or owning property in an area. Subsequently, elections are held to approve the district and to vote bonds for financing the construction of facilities.

In both water control and fresh water supply districts, general obligation bonds are voted; interest rates on these bonds can be lower than those based on revenue alone, and they are more marketable.

Fresh water supply districts are established by filing a petition with the county commissioners court. The court, after a hearing, can create the district. Elections are then held to approve the district and vote financing bonds.

Originally, the fresh water districts were formed when effluents from septic tanks and privies caused pollution. Some Harris County subdividers, however, set up districts for their development before building many houses. The districts can be created with only five people in the area to vote the money for the

entire subdivision's water and sewerage systems.

This district's advantages: its bonds can be sold and the subdivider need not keep money invested in facilities; bonds sold at 90 percent of face value often go to par or above when a city assumes the district's obligations; a city can annex a district simply by assuming the system's liabilities and operation.

Subdividers unable to borrow money to install water and sewerage systems in their developments used their own funds to provide these services.

Subdividers obtained services by arranging with a contractor to install the water supply system, sewerage, paving, and street lights in return for a lien on the property, by putting in water and sewage lines so that existing systems could be extended to the new developments, or by building and operating these services themselves.

These private systems, although planned in their entirety, generally were built piecemeal. Lines were installed as needed and some sewage treatment plants were constructed in stages, although providing complete treatment at each stage.

Similarly, water lines were put in street by street, and water supply plants began with one well and pressure tank, adding tanks with high lift pumps, additional wells and storage tanks, or another plant as needed.

These methods were developed over several years. When the county's suburban development began, each subdivider financed water and sewerage systems his own way. The subdividers realized the advantages of community systems over septic tanks and private wells, although the initial cost was about the same.

During the building boom, many water and sewerage systems made money in their first year of operation. Now, however, Moehlman said, building rates seem normal or below normal in Harris County, fewer homes are sold, and small pri-

vate utility operations take longer to become self-supporting.

Survey Made

A survey of installation costs, operating costs, and revenues showed that installing water and sewage disposal services in districts where homes were already built cost more per connection than when the subdivider constructed the facilities.

The developers built on every lot in their subdivision, while the water districts serve only existing homes. One water district had facilities for 2,789 lots, but only 1,230 homes were connected to the lines after a year's operation.

According to Moehlman, installing water and sewage facilities in the water district cost \$348 per lot, in the subdivision, \$340. But the cost per connection in a water district was \$790, while the subdivider paid a smaller sum for each connection, he pointed out. The district's taxes and other revenue must offset this larger capital outlay and yearly expense. However, as more homes were built on once vacant lots, taxes and rates decreased.

The privately owned systems adopted existing city or water district rates without knowing operating costs or potential returns. Competing subdividers offered free water for a year as a buyer inducement, or halved rates to nurture beautiful green lawns in one development.

With careful planning, engineering, construction, and operation, even small water and sewage disposal systems need not be a detriment, Moehlman declared.

He concluded that Harris County's numerous water and sewerage systems for the subdivisions were not ideal. In some ways the multiple systems are only a step above using septic tanks and private wells. But they suit the county's present situation.

Ultimately the city of Houston could annex all these systems and eliminate many small sewage treatment and water supply plants.

After advising against exaggerating and overpublicizing the promise and hazards of nuclear energy, Morton concluded that "the logical objective is to deal with the radiological health and environmental control problems as they now exist, to study and learn more about the fundamental factors involved, and to develop rational methods of control that are as conservative and adaptable as possible."

Clean Water Law Aids 700 Communities

About 700 communities were offered Federal aid and 600 others applied for grants during the first year the Federal Water Pollution Control Act of 1956 has been in effect.

Robert R. Harris, chief, Construction Grants Section, Water Supply and Water Pollution Control Program, Public Health Service, discussed this and other consequences of the legislation.

New facilities and improvements to existing sewage works costing more than \$250 million have already been aided by this act. Federal contributions for the first year reached \$56,237,000; a ratio of 4 local dollars to each Federal dollar, Harris stated. The law limits the Federal share of grants to \$250,000 or 30 percent of the cost, whichever is less.

He noted that the \$95 million appropriated for grants during the first 2 years is far short of the amount communities have already requested.

The Federal grants have made their biggest impact upon small communities, Harris stated. The first 127 Federally aided sewage treatment plants in 7 midwestern States will reduce pollution from municipal sewers in 1,700 miles of streams to satisfactory levels. Ninety percent of the communities these plants serve have populations under 25,000.

The legislation provides that half the grant funds must aid communities of 125,000 or less; 84 percent of the funds already allotted have gone to communities in this category.

State Participation

The most significant feature of the act, Harris said, is the reaffirmation by Congress of the States' primary right and responsibility to prevent and control water pollution. Federal activities primarily support and supplement the efforts of State and local agencies.

Municipalities wishing Federal aid must first apply to their State water pollution control agency. The State approves the application and certifies that the proposals it contains have priority over others in the State.

The act specifies that the priority must be based on financial as well as water pollution control needs. A Federal grant offer is made subject to the terms and conditions specified by the State and the Public Health Service.

Financing methods the communities have used depend upon their fiscal resources and State laws. General obligation bonds, certificates, or warrants payable from ad valorem taxes of a municipality are most popular. But revenue bonds and certificates and special assessment bonds have also been used. Often a community raises funds from several sources such as unencumbered cash, proceeds from several types of bonds, Federal loans, and grant moneys from State and Federal governments.

Several State governments now offer assistance to communities. Partly stimulated by the Federal Water Pollution Control Act, the Maine, Maryland, and Vermont legislatures in 1957 established supplementary grant programs. New Mexico voted special assistance to rural unincorporated areas, and Ohio created an emergency Village Capital Improvement Rotary Fund to make advances for planning.

New York, Pennsylvania, California, and Oregon already had some form of State assistance.

Law's Impact

The act contains broad definitions: treatment works include interceptor

and outfall sewers, pumping, power, and other equipment, as well as extensions, improvements, remodeling, additions, and alterations of existing treatment works; construction includes preliminary planning, necessary engineering, architectural, legal, and fiscal investigations and services, preparation of designs, specifications, and plans, and inspection and supervision of the construction.

As a result, Harris said, many treatment works not otherwise possible are being built through combined Federal, States', and local governments' efforts.

The Federal grants already offered will aid sewage treatment plants serving 10,500,000 people and an estimated 14,900,000 in the future. Harris pointed out, however, that some 9,000 communities need new or improved facilities.

The Nation's annual per capita expenditure for construction of municipal sewage treatment works is about \$2.42, based on the 1950-54 average. Even if this rate is maintained until 1985, the population equivalent of sewage still delivered to streams then will be 25 million higher than it is today, Harris stated.

Bonds Finance County Water, Sewage Plants

Methods used to finance the 97 sewage treatment plants and 150 water plants in Harris County, Tex., were described by Roger Moehlman, sanitary engineer, Harris County Health Unit.

Outside Houston, with its 900,000 population, 200,000 people live in small cities and unincorporated areas where suburban development has mushroomed since 1945. In these fringe areas 15,000 lots were subdivided in 1955, 13,000 in 1956. Water supply and sewage disposal facilities were lacking, and most suburban developers had to provide these services for their own subdivisions.

Septic tanks and shallow wells

The pH also affects pressure. A 5.5 pH is usually maintained for well injection. To improve filtration the pH was raised to 6.0 or 6.5. But the pH increase raised the maximum pressure to 900 or 950 pounds. Returning to a 5.5 pH brought the pressure to 800 within a couple of months. This indicated to Wallace that a low pH was necessary to maintain the openings in the strata through which the waste is injected.

The injection process also works against the normal head of approximately 750 pounds needed to push the waste into the voids. Wallace believes the present wells will continue to operate satisfactorily until the void is filled.

Sanitation Experts Can Cut Accidents

Accident prevention is the responsibility of the total public health program, and the local environmental health group has several opportunities to make a major contribution, according to Eugene L. Lehr, chief, Program Services, Accident Prevention Program, Public Health Service.

The skills of the public health engineer and sanitarian in observing and correcting environmental sanitation hazards may be readily extended to environmental accident hazards. There are six stages, Lehr suggested, where accident prevention measures may be applied with environmental operations:

1. In the investigation of nuisance complaints the concept of home safety can be brought directly to the attention of households.

2. When food processing or handling plants are inspected, safety can be promoted as well as cleanliness.

3. Sanitarians conducting insect and rodent control have the opportunity to detect accident hazards and to advise or assist on corrective measures. At the same time, they also have the opportunity of exploring the subject of accidental poisonings.

4. Since the sanitation section frequently plays a leading role in the regulation and inspection of institutional facilities it has the opportunity to detect and eliminate accident hazards there.

5. Recreational facilities, especially neighborhood and private swimming pools, require more than advice and assistance on water treatment. They are sources of many accidental injuries.

6. Finally, the sanitary engineer and sanitarian can contribute materially to the study of housing in his community, and to the establishment of neighborhood improvement campaigns, urban rehabilitation programs, and housing codes designed to prevent the deterioration of existing housing as it ages and as conditions of occupancy change.

Aerosol Methods Applied To Drinking Fountains

Aerosol studies will tell us if drinking fountains are a potential vehicle of disease transmission, according to Dr. W. N. Mack, professor

of microbiology and public health, Michigan State University.

Preliminary investigations show, Mack said, that viable virus particles can be recovered by the aerosol method. After feeding T₃ bacteriophage into an angle jet stream of a drinking fountain, 630 liters of air from surrounding areas were collected at 5-minute intervals, 14 inches above the rim of the bowl. Three samples out of five contained 2.1, 52.0, and 2.3 virus particles per liter of air tested.

Aerosols from the splash of the drinking fountain produced inconsistent amounts of virus, Mack said, because drops of water from the fountain were influenced by the sampler's air flow, and the fountain did not produce an evenly dispersed atomization of virus. The distance at which viable virus particles may be collected, he reported, is at least 48 inches from the apex of the stream and in the opposite direction from the flow.

To determine whether the drinking fountain is a potential health hazard or not, Mack pointed out that the sanitarian need only apply the available tools and methodology.

Chronic Diseases . . .

National Program Aids Cancer Chemotherapy

The national cancer chemotherapy program, initiated in 1953, comprises one of the greatest mobilizations of resources ever undertaken to conquer a single disease, said Dr. Kenneth M. Endicott, chief, Cancer Chemotherapy National Service Center, Public Health Service. Both government and private agencies have joined forces in this program of accelerated research on cancer chemotherapy through encouraging voluntary cooperative studies in certain areas and at the same time supporting individual investigators

Sponsoring agencies of the program are the National Cancer Institute, the American Cancer Society, the Damon Runyon Memorial Fund for Cancer Research, the Veterans Administration, the Atomic Energy Commission, and the Food and Drug Administration.

Program Organization

One of three groups under which the program has been organized is the Cancer Chemotherapy National Committee. This policymaking group is composed of a member from each of the sponsoring agencies, a member-at-large, and a member from the pharmaceutical industry.

Another group is the Industry Sub-

However, pending any such move, fringe areas outside the city will need more small plants, he said.

Perhaps a countywide sanitary district to handle all water and sewage disposal services would be best, Moehlman stated.

Attempts Made to Measure Effects of Air Pollution

Air pollution in many cities around the world has created a substantial health problem, said Dr. Lester Breslow and Dr. John Goldsmith, bureau of chronic diseases, California State Department of Public Health.

But, they went on to say, "if we are to attack air pollution as an environmental influence detracting from health as well as causing disease and death, then it seems desirable to measure the extent to which it does interfere with well-being."

In 1956, in an attempt to measure the effects of air pollution on health, the California State Department of Public Health sampled 3,545 households. Forty percent stated they were bothered by air pollution. In Los Angeles County, 60 percent reported various unpleasant physical reactions. The surveyors found that 1 out of 8 Los Angeles households was considering change of residence because of air pollution, while some were thinking of changing their jobs for the same reason. Commenting on this situation, Breslow and Goldsmith said, "Interference with well-being to the point of changing residence or job represents a disruption of health which certainly qualifies smog as a public health problem."

The possibility that air pollutants are causally related to lung cancer and respiratory diseases has led to several studies here and abroad, and, the authors noted, the English have had some success in relating chronic bronchitis to air pollution.

Attempts to measure the relationship of air pollution to chronic diseases in this country, however, have

not been conclusive, according to Breslow and Goldsmith. An investigation in 1956 to confirm the impression that episodes of smog precipitate asthma was inconclusive.

Since 1954 the California State Department of Public Health has been studying daily mortality data from Los Angeles, but has not as yet demonstrated any effect of air pollution on mortality. A special study of 4,000 nursing home patients, who, the authors believe, would quickly reflect any adverse environmental condition, has revealed no definite effect on mortality from air pollution alone. But, the authors admonish, this does not mean that no effect occurred.

Present knowledge of the health implications of air pollution demands strenuous control efforts, but Breslow and Goldsmith stressed the fact that "research on the health effects must be pursued with equal vigor in order to identify the aspects of air pollution which are most dangerous to human life and well-being."

Deep Wells Found Practical For Waste Disposal

Deep wells are the cheapest, most practical method of disposing of chemical waste, stated W. H. Wallace, fine chemicals department foreman, Upjohn Company, Kalamazoo, Mich. The company now pumps 25 million gallons of waste per year into the substrata at a cost of \$2 per 1,000 gallons.

The firm turned to wells in 1954 when the swampy area, previously used for disposal of wastes from fine chemical production and processing, became seriously contaminated.

It is generally agreed that a successful disposal well must be located in a favorable geologic structure, such as sedimentary rock formations, including sandstones, limestone, and dolomites, he said. These strata are often several thousand feet thick in the North Central States. Their porous capacity is large; wells pump

into a substrata approximately 15 percent void.

Disposal Wells Favored

According to Wallace, Michigan's State regulatory body, the Water Resources Commission, favors using disposal wells if they are cemented in and properly constructed. The State's geological division does not fear contamination of the potable water strata when the disposal well discharges at 1,000 feet below the well water aquifer.

The company's first disposal well, drilled in 1954, was an 8-inch well with a 7-inch steel casing inside and the area between sealed with concrete. As additional protection against contamination, waste is pumped through a 2-inch, high-pressure line, sealed at the top and bottom of the well. A leak in this line is instantly detected by watching the pressure developed in the annular space.

The cost of the well method is higher than the cost of biological disposal. But the large amount of lime neutralizer used was also necessary in the previous system, because the concentrated waste has an extremely high chemical oxidation demand. Liquid waste must be neutralized, clarified, and filtered before being pumped into the wells. If another well and injection pump were added, the cost per 1,000 gallons would decrease since the present labor force could handle 50 to 75 percent more volume.

Useful Life

Disposal wells always lead to the question of how long they will last. Upjohn may have a partial answer from its 3 years' experience.

The company uses 2 high-pressure injection pumps operated together and singly, 6 days a week, and records each day's maximum and minimum pressure. At the start, the maximum pressure was approximately 980 pounds per square inch and the minimum, 500. Today the maximum has dropped to 800 pounds, but the minimum is 750.

given in effective dosages, he said. The cooperative studies, Moore advised, should yield valid information in the shortest possible time with the least possible risk to patients.

In the first studies, cancers of poor prognosis were selected for observation. The parallel investigations at a large number of hospitals were planned to insure an adequate number of study patients within a 1-year period.

Triethylenethiophosphoramide (TSPA) is under test in conjunction with surgery for carcinoma of the stomach in one study. A second study concerns the use of nitrogen mustard in patients with resectable lung cancer.

Under consideration are studies of colon and rectal carcinoma and breast cancer, using TSPA, and cancer of the ovary, using an alkylating agent or radioactive isotope.

Study Protocol

Moore outlined as representative the protocol of the gastric cancer study, followed in the separate investigations by the various hospitals. Patients with nonresectable lesions or physical conditions that indicate increased risk to chemotherapy are excluded. Eligible patients are assigned by random selection to experimental and control groups, with the assignment unknown to the surgeon until after completion of the excision.

At surgery the scheduled dosage is administered into the systemic vein and into the peritoneal cavity before closing the abdomen. Post-operative dosages are given intravenously on the 1st and 2d days.

Followup examinations are designed to obtain immediate information on the effect of the chemotherapeutic agent upon the blood-forming system and to yield subsequent information on survival. Survival was adopted as the only criterion of effectiveness.

Moore stressed the importance of the central statistical unit, which must provide the randomization techniques, index patients admitted to the study, check on the accuracy

of the data gathered, verify survival periods, and, finally, assess the value of the therapy.

Final assessment of Triethylenethiophosphoramide as an adjuvant agent against carcinoma of the stomach should be possible within 2 years after completion of the study, Moore said.

Environment Holds Brain Tumor Clue

The first study on the epidemiology of tumors of the central nervous system showed that an environmental factor may be associated with these tumors, according to Dr. Thomas F. Mancuso, chief, division of industrial hygiene, and Dr. Elizabeth Jackson Coulter, chief statistician, division of vital statistics, Ohio Department of Health.

The authors, using data on residents of Ohio, 25 to 64 years of age, who died of tumors of the central nervous system during the period from 1944 to 1952, found variations according to geographic location, population group, and industry. Death certificates, histological examinations, X-rays, angiograms, and ventriculograms were the sources of their data.

High Urban Rate

Data on residence of white males showed that the 8 metropolitan counties had a standardized mortality ratio of 110.1, that 7 urban counties had a 97.3 ratio, and that the remaining 73 rural counties had an 84.4 ratio compared with the whole State. Counties were classified as metropolitan if they had cities of 100,000 or more; as urban if they had 50,000 or more persons living in urban areas.

In Summit County, Ohio, deaths of white men due to brain tumors were significantly higher than expected on the basis of mortality experience in the State—77 compared with 53.8. For white men, Summit County's average annual

age-adjusted rate, 8.06, was the highest among Ohio's 8 metropolitan counties, whose total rate was 6.26.

The metropolitan counties had 602 deaths due to tumors of the central nervous system among white men, and 415 among white women of the same age group during the 1944 to 1952 period.

These counties, the authors also found, had a higher average annual mortality rate per 100,000 for men than for women. The age-adjusted rate for the counties for men was 6.26 compared with 4.22 for women. In each county the rate for men exceeded that for women.

Mancuso and Coulter compared average annual death rates per 100,000 for native white, foreign born white, and nonwhite males. The age-adjusted rate for foreign born was 5.89, for native white 4.25, and for nonwhite, 3.17.

Data on length of residence in the metropolitan counties at the time of death showed 45 of 81 foreign born white males and 215 of 367 native white males died after 20 or more years of residence.

Industry as a Factor

Variations by industry and length of employment were also factors in deaths from brain tumors, the authors reported. Their statewide data covered 934 white males who died of tumors of the central nervous system in the period 1944-52. The employment histories of each death were reviewed to determine the industry in which the person worked in 1939, by age at that time.

In addition, the period of employment in the industry recorded in 1939 was determined. Industry rates of employment in 1939 were computed on the basis of population data in the 1940 U. S. census and adjusted for age on the basis of the total population of continental United States.

Deaths due to tumors of the central nervous system were identified in three major industry groups of agriculture, construction, and manufacturing. Within the manufactur-

committee which advises on industrial problems and promotes industrial participation in cancer chemotherapy research. It is composed of industrial research executives who serve as private individuals and not as company representatives.

The Cancer Chemotherapy National Service Center, the third group, has a full-time staff which administers the program recommended by the national committee, organizes and operates the needed technical advisory panels, arranges for the exchange of information, promotes cooperation among scientists, and otherwise implements the national program.

The existing program is a mixture of empiricism, exploration of existing leads, and support of that basic research which appears to offer the possibility of yielding useful information, Endicott stated. At present too little is known of the nature of cancer and the agents that temporarily inhibit its growth to allow discarding any likely material without at least a preliminary trial, he said.

National Service Center

To give the program direction, the center established five technical advisory panels: chemistry, screening, pharmacology-biochemistry, endocrinology, and clinical studies.

Some 45,000 materials are sent annually to the center for antitumor test by research organizations, universities, and pharmaceutical and chemical companies. These materials are screened against three types of mouse cancer—sarcoma 180, carcinoma 755, and leukemia L1210—especially chosen for their ability to indicate anticancer agents. Six screening laboratories are under contract to the center, and negotiations are under way with several pharmaceutical companies for implant screening.

For the development of better screening methods, microbiological methods, tissue culture, and human tumors in animal hosts are under study. Also being sought are reliable biochemical techniques for in-

dicating the cancer destroying properties of chemicals, hormones, and antibiotics.

When a pharmacological compound is found to have anticancer activity in the screening, animal studies are made to see what happens to the drug in the body. Before human trial is initiated, proper dosage and toxicity are determined.

Clinical trials are made by 11 cooperative study groups which represent more than 100 medical schools and hospitals in different parts of the country. End results are analyzed through tumor registries which are set up to provide data annually on all types of cancer and to undertake special studies on the effect of various treatments.

For better communication of research findings, a documentation center for information on cancer chemotherapy has been established at the center. A current bibliography, beginning with 1946, is available, and a series of reports are being issued to qualified investigators.

Other services offered by the center include procurement of chemicals and radioactive compounds for research purposes, arrangements for screening, pharmacological studies, and arrangement of interinstitutional cooperative clinical trials for large-scale evaluation of promising compounds. Information on technical problems as well as on grants, fellowships, and travel funds is also provided.

Industrial participation, which has been mainly limited to the submission of compounds, will be expanded through contracts made possible by recent congressional appropriation, Endicott reported. Firms will undertake research and development projects as well as "target" or applied programs. Work will cover implant screening, syntheses of potential anticancer agents, pharmacology, methodology, and other phases of drug development.

Evidence that the clinical course of cancer can be influenced by chemicals has aroused the interest and support of the pharmaceutical industry, research organizations, private

investigators, and the Government. The cooperation of these groups makes possible a continuous, concerted effort toward the chemical control of cancer, Endicott concluded.

Anticancer Agents Tested As Surgery Adjuvant

The efficacy of anticancer agents as an adjuvant to excisional surgery is on trial at a group of university surgery departments and a group of veterans hospitals.

These closely supervised studies, organized in November 1956 under the auspices of the Clinical Panel of the Cancer Chemotherapy National Service Center, were described by Dr. George E. Moore, director of the Roswell Park Memorial Institute, Buffalo, N. Y.

Surgery, even when all gross evidence of the tumor is removed, and irradiation of the operative area do not cure all patients, Moore said. He pointed out that free tumor cells may spread through the lymphatic and vascular systems, or they may exfoliate into a body cavity. About half of the blood samples obtained from veins draining malignancies of the lung and gastric intestinal tract contain tumor cells, he reported.

Moore termed logical an attempt to destroy by chemical compounds the widespread cancer cells remaining after surgery since the majority of patients die from metastasis of the cancerous cells rather than from local recurrence.

In experimental work, he reported, chemotherapeutic agents have been effective against unestablished tumors, although they were ineffective in curing the same type of established tumors.

Highly Toxic

Moore warned, however, that adjuvant chemotherapy has not been established and is not recommended for general use. With few exceptions, all compounds active against tumors are extremely toxic when

225 cases were identified as actual cases through records or interview.

202 cases qualified under Jones' diagnostic criteria.

113 cases were in females, 112 in males.

152 cases were in children under 15 years of age.

41 of the physicians were general practitioners, 15 internists, 7 pediatricians, and 2 surgeons.

Interview data from 240 physicians who did not return questionnaires showed:

74 physicians treated 177 cases of rheumatic fever.

158 cases qualified as actual cases under Jones' diagnostic criteria.

65 cases were in females, 112 in males.

114 cases were in children under 15 years of age.

105 of the physicians were general practitioners, 30 surgeons, 28 internists, 10 pediatricians, and 67 others eye, ear, nose and throat specialists, dermatologists, psychiatrists, urologists, orthopedic surgeons, obstetricians, gynecologists, or radiologists.

Reports from the two groups of physicians showed differences in percentages of cases meeting Jones' major and minor criteria for rheumatic fever.

But in the reporting group 52 percent of the cases met 2 major criteria, and 38 percent met 1 major and 2 minor criteria. In the nonreporting group 45 percent of the cases met 2 major criteria, and the same percentage met 1 major and 2 minor criteria. Under Jones' criteria 90 percent of the cases in both groups qualified as rheumatic fever.

In both groups general practitioners diagnosed and treated 75 percent of the cases and internists and pediatricians 20 percent. Two-thirds of all cases of rheumatic fever occurred in children under 15 years.

Conclusions

The followup studies, statistically designed to confirm or revise the

2,297 cases originally reported in the survey, proved to Rosenfield that 1,650 cases were actually treated by the entire group of physicians returning questionnaires.

The interviews with the 240 physicians who had not returned questionnaires showed 74, or 30.8 percent, had treated rheumatic fever, while 597, or 39.3 percent of those replying in the survey, reported cases. This indicated the 1,507 non-responders in the original survey treated approximately 1,000 cases.

Rosenfield concluded that Minnesota had 2,600 cases of rheumatic fever in 1955, that the disease continues to be prevalent in the State, and that it constitutes a serious hazard.

Recurrence Rates Decline For Rheumatic Fever

Rheumatic fever recurrence rates in patients aged 2-20 years showed a decline during a 21-year study, 1936-56, conducted at the New York Hospital cardiac rheumatic clinic.

According to Dr. May G. Wilson, Dr. Wan Ngo Lim, and Dr. Ann McA. Birch, all pediatricians with the Cornell University Medical College, the decline appeared to coincide with progressive improvement in socioeconomic status for the observed patients.

The downward trend in recurrence rates antedated the antimicrobial era and did not appear to be sharper

for 1952-56 when antibiotics were administered either therapeutically or prophylactically, the authors stated.

During the study period 782 children, who contributed 5,663 person-years, had a total of 613 recurrences, giving a crude overall rate of 10.8 percent per year. Twenty-one consecutive annual recurrence rates at ages 2 to 20 years gave a mean rate of 9.8 percent per year. There was a statistically significant downward trend, with a slope of -0.4 percent per year, in the annual recurrence rates from 1937 to 1956. The individual rates for 1936-41 were significantly above the mean rate, and significantly below for 1955-56.

The approximate chance of a recurrence in any one year for all children 6 to 13 years of age declined from 1 in 4 before 1944 to 1 in 7 between 1944 and 1956. For those aged 14 to 20 years the chances fell from 1 in 16 to 1 in 35.

General improvement in the standard of living in Greater New York City during the years 1936-56 was reflected in the socioeconomic composition of the clinic population, the authors stated. They explained that the relative percentage of patients in the best environmental group increased, and those in the poorest socioeconomic status decreased. Recurrence rates were generally lower in the more favorable environmental group, and for the poorest environmental group the rates did not follow the decline noted for the total clinic population.

Dental Health . . .

Fluoridation System Devised for Home Use

Users of private water supplies may soon be able to enjoy the benefits of fluoridated drinking water, according to statements by F. J. Maier, sanitary engineer, Division of Dental Public Health, Public Health Service.

For the past 2 years, a device for fluoridating individual water systems has been in use in four suburban homes in Maryland. Fluoridation has been accomplished with the utmost safety and with remarkable consistency and precision, the report indicated.

Indispensable to satisfactory operation of home fluoridation equip-

ing group approximately 10 specific industries were studied. The result showed considerable variation in rates. The lowest rate for the three broad industrial groups occurred in agriculture. Several specific manufacturing industries, on the other hand, showed relatively high mortality.

On the basis of their data, Mancuso and Coulter concluded that exploration of environmental factors may provide clues to the etiology of tumors of the central nervous system.

Finds Ethnic Extremes In Cervical Cancer

Cancer of the uterine cervix is nearly four times as common among non-Jewish white women of New York City as in Jewish women of either New York or Israel.

Incidence rates are consistently low for cancer of the cervix—4.8 per 100,000—among Jewish women in both areas although habits, customs, and geographic origins of the two groups are not identical. By contrast, the rate for non-Jewish white women in New York City is 17.3, and it is 39.1 for selected urban areas in the United States.

These findings were reported by Dr. Lucia J. Dunham of the Laboratory of Pathology, National Cancer Institute, from studies pursued with Dr. Harold F. Dorn, chief, Biometrics Branch, National Institutes of Health.

Cervical cancer seems to be a frequent form of malignancy in Puerto Rican and nonwhite women, according to Dunham and Dorn. The incidence for Puerto Rican women was 111.3 per 100,000 while the rate for nonwhite women was 54.5 per 100,000 in the groups studied in New York City.

Individual interviews of patients were conducted to obtain information on social, medical, surgical, menstrual, marital, and pregnancy histories. A total of 3,514 women, including 2,418 Jewish women and

1,096 non-Jewish white women, were interviewed between 1951 and 1953 in New York City and Israel. Fewer than half of them had cancer. The remainder were hospital patients without cancer, interviewed as control cases.

Durnham and Dorn emphasized that this is a preliminary report on the methods used in a study of women with uterine cancers in different geographic areas and racial groups. "We hope a scientific basis will be established for the study of factors which may shed light on reasons for differences in cancers of the uterine cervix in several population groups," they said.

Cytological Facilities For Cervical Lesions

A widespread deployment of cytological diagnostic facilities would be of invaluable assistance in the early detection and treatment of cervical lesions, presumed to be a preinvasive form of cancer. Of equal importance, these facilities would enable us to arrive at an understanding of the biology of cervical carcinoma and its epidemiology.

These were the main contentions of Dr. John K. Frost, assistant professor of gynecology, Johns Hopkins School of Medicine, and associate professor of pathology, University of Maryland School of Medicine, Baltimore.

Through the use of exfoliative cytology, he said, the preinvasive form of cervical cancer has been detected in 97 percent of the women in whom it is known to occur. This may be contrasted with the disappointingly infrequent detections by physical examination alone.

Cytological detection of these lesions of carcinoma-in-situ, has resulted in early treatment, which Frost believes has contributed increasingly to the conservation of life.

But there is still some distance to go, Frost observed, before the biological behavior of cervical lesions

is completely understood. Establishing adequate cytological diagnostic facilities would shorten that distance considerably.

Rheumatic Fever Cases Exceed Morbidity Reports

A study of rheumatic fever prevalence in Minnesota showed that 2,600 cases were diagnosed and treated in 1955, although 187 cases is the State's yearly reported average (1950-54).

Reporting of the disease is required by law, but such reporting is known to be incomplete, stated Dr. A. B. Rosenfield, director, division of special services, Minnesota Department of Health, who made the study.

To obtain accurate information on prevalence, Minnesota's Heart Association, the State Department of Health, and the Heart Committee of the State Medical Association sent questionnaires to 3,063 State Medical Association members in September 1955.

In 1,519 replies, 597 physicians reported 2,297 cases over 12 months, averaging 3.8 cases per physician reporting cases.

The large number of cases reported in the survey and the small number reported to the State health department raised two questions, Rosenfield declared. How many of the 2,297 cases were actually identifiable? How many met accepted diagnostic criteria for rheumatic fever?

Physicians Interviewed

To find the answers, 65 physicians (11 percent) who reported 13 percent of the cases in the survey and 240 physicians (16 percent) who did not return questionnaires were interviewed. Case records were also reviewed and data abstracted on a checklist of Jones' criteria for diagnosis of rheumatic fever.

Interview data from 65 physicians who returned questionnaires showed:

281 cases of rheumatic fever were reported.

same kind of care he customarily applies to other water treatment processes.

Accuracy in fluoride feeding may be difficult in some instances, but it is never impossible.

Major direct responsibility for surveillance of the fluoridation process belongs to the health department engineer. Dentists, however, are indirectly accountable, the report pointed out. They have predicted and promised benefits. Their indifference to the necessity of maintaining a precise fluoride level could bring them discredit should fluoridation be condemned because inadequate procedures produced inadequate results.

Responsibilities for Dental Hygienists

Increased responsibilities would attract more dental hygienists to public health service, commented Martha Howard Fales, dental health coordinator, Brookline, Mass.

The primary reason for the shortage of dental hygienists, Fales maintained, is that few are given the opportunity to use their capacities to the full, with the result that their work seems unattractive.

Recruitments, Fales said, are not replacing those lost through death or retirement. As a result, more and more public health dentists have had to undertake duties normally performed by the hygienist.

Responsibilities, Fales observed, may be added to the dental hygienist's role according to the level of competency. There are three such levels: the certificate dental hygienist, the dental hygienist with a bachelor's degree, and the dental hygienist with graduate training in public health. Fales suggested the following responsibilities that could be assigned to each level of competency.

Certificate Dental Hygienist

Educate patients, particularly children, in dental procedures and dental health facts.

Educate patients in the requirements and routines of the clinic.

Screen clinic cases from referrals to private dentists.

Conduct community dental surveys.

Take roentgenograms for community surveys or for research studies as well as in the clinic.

Do all prophylactic work for clinic patients or for demonstration programs.

Make topical fluoride applications.

Make occlusal evaluations, code findings, and make models.

Take charge of clinic supplies, and inform staff of availability of new materials.

Degree Dental Hygienist

Screen patients; record and interpret findings for others.

Compile data on clinic functions and activities for the director.

Undertake major load of school dental health programs.

Provide and interpret information for local groups.

Act with or for the director in planning community projects.

Work with welfare, volunteer, and veterans' groups.

Lecture before training schools and supervise field training experience.

Graduate Dental Hygienist

Administer town or county dental programs, coordinating the work of advisory dental committees with dental clinic programs.

Participate in program planning and evaluation.

Recruit for staff openings.

Train new personnel.

Help prepare annual reports and budget.

Arrange field training visits and institutes.

Work with dental hygiene training schools and teacher training colleges.

Urges States to Meet Dental Deficiencies

The inadequate supply of dentists and dental hygienists makes it man-

datory for State health agencies to play a larger role in dental health activities than they have up to now, commented Dr. Wesley O. Young, director, division of dental health, Idaho State Board of Health.

State health agencies, Young said, must stimulate interest and action, coordinate joint cooperative action on State, regional, and national levels and serve as a source of technical information.

Since the basic objective of public dental health is to improve the oral health of the public through community activities, it is imperative, Young asserted, that the supply of dental personnel be increased and the available resources be fully utilized in order to meet that objective.

Various attempts, Young noted, have been made to meet the widespread lack of dental manpower. Fluoridation and emphasis on child dental care are two activities undertaken to reduce anticipated patient loads. In the western States, to which Young turned for his examples, expansion of present facilities, reorganization of various units, and creation of new methods have been the principal activities in meeting the problems of dental manpower shortages.

In Colorado, Young said, the new dental school being built there will be, through the efforts of the State dental society, regional in character and will serve the entire Rocky Mountain area. In Idaho, the State dental society has provided scholarships for students of dental hygiene, and plans have been developed to expand one of the universities to include a dental hygiene school. This school will offer courses leading to a certificate or a degree in dental hygiene. In Nevada, the uneven distribution of its population resulted in inadequate dental care in sparsely populated regions. To serve these relatively isolated areas, the State dental society purchased a fully equipped dental trailer.

In order to provide adequate dental manpower, four basic steps must be taken, Young said: (a) de-

ment is proper maintenance, Maier said. A service to provide fluoridated water similar to services now providing chlorinated water, softened water, or bottled water was recommended as a practical and profitable enterprise.

The tasks of a fluoridation service would include analysis of the untreated water; provision, installation, and maintenance of equipment; periodic inspection of the installation, replenishment of the fluoride solution, and adjustment of the dosage; and eventually removal of the equipment.

The cost for the service, including a \$1.50 profit, is estimated to be \$3.00 per month. It could be less, depending on the number of customers, distances traveled in servicing the equipment, and the like.

So far fluoride-feeding devices are available only for homes with electrically driven pumps which discharge into a pressure tank, but devices can be developed for other types of private water supply systems.

In the Maryland experiment, two types of feeders have been tried. One is actuated by a solenoid which is energized periodically through a rectifier by means of an electric timer. The other is hydraulically operated, the driving energy being derived from the water pressure in the distribution system.

These two types, both commercially available, appear to be equally accurate, but the hydraulic model seems to operate more smoothly, according to Maier. With the hydraulic model, he pointed out, there is no possibility of operation when the pump switch is on but no water is being delivered.

During most of the testing period, the units were serviced each month, although replenishment of fluoride solution was not required for about 3 months. Minor repairs, such as replacement of fuses, repair of leaks, or replacement of plastic parts, had to be made occasionally. These affected the continuity of feeding, but they did not affect at all the

safety of the procedure from the standpoint of overdosing.

Maier estimates that currently about 20 million homes housing 60 million people have private, individual water sources, and he believes the proportion is increasing slightly each year.

Topical application of fluorides, use of bottled fluoride water, and use of pills containing fluoride are among the methods suggested for bringing the benefits of fluoride to these people. But these methods, according to Maier, are expensive, difficult to administer, or hazardous in comparison with fluoridation of the water supply.

All known experience and information indicate that fluoridation of the existing water supply is the best method from the standpoint of both safety and effectiveness.

Precision in Fluoridation Judged a Necessity

Maximum benefit to teeth from fluoride depends on maintenance of the fluoride content of the water supply at the established optimal level, declared Grace C. Scholz and Floyd B. Taylor, of the Public Health Service, and W. L. Harris, water plant supervisor in Grand Rapids, Mich. Miss Scholz is chief of statistical services, Division of Dental Public Health, and Mr. Taylor is sanitary engineer, Division of Sanitary Engineering Services.

Reporting a study which revealed that two cities failed to keep the fluoride content up to the desired level, they urged periodic, current determinations of fluoride content and immediate correction of deficiencies. They recommended simple statistical analysis of series of water test results, preferably at intervals not exceeding 3 months.

Fluoridation as a public health measure will not be judged by the maximum results that a properly conducted study can effect but by its actual achievement in preventing dental caries in all communities where it is practiced, they warned.

It was observed that State health departments frequently establish recommended levels of fluoride concentration and a maximum level that is never to be exceeded, but that little concern is evidenced when fluoride concentrations fall below the recommended level.

The study was conducted in two unidentified cities in the east and in Grand Rapids, Mich. It was based on water sample analyses performed and recorded as part of normal plant operations.

Grand Rapids achieved remarkable precision in meeting the objective of 1.0 to 1.1 p.p.m. fluoride. In clearwell samples, the mean fluoride content during a 10-year period was 1.07 p.p.m., with a standard deviation of only 0.06 p.p.m. Findings for samples from the distribution system during the same period were comparable.

The two eastern cities, however, fell far below their fluoridation aim. In one the mean for samples from the distribution system collected during a period of more than 2 years was 0.62 p.p.m. with a standard deviation of 0.23 p.p.m. This city ceased fluoridation by action of the governing council following suspension of the procedure by the water superintendent.

In the other eastern city, the mean for distribution system samples was 0.66 p.p.m., and the standard deviation was 0.41 p.p.m., indicating a wide variation in the readings. Samples collected at the pumping station during a portion of the same period showed a mean of 0.76 p.p.m. and a standard deviation of 0.32.

Officials in this latter city introduced corrective measures, and a subsequent 6-month series of samples showed improvement. The mean was 0.88 p.p.m. with a standard deviation of 0.26 p.p.m.

It was noted that the fluoridation experience of the two eastern cities is not unique.

Fluoridation procedure presents no unusual technical difficulties, the report stated, but it requires that the water plant operator exercise the

ords, recruitment and utilization of personnel with special competence in records work, increased understanding and support of records work by administrators, and expansion of training facilities specifically designed for public health records personnel are some of the steps needed to improve health department reports and records, Lucas stated.

Records Systems

Each element of a records system must be selected for its contribution to the whole because a breakdown in any one element will affect the functioning of the entire system. According to Lucas, obsolete procedures, lack of attention to schedules for the disposition and retention of records, and delay in the progression of records from point of origin to final filing are some of the problems of records systems.

Lucid, concise, up-to-date procedures manuals are essential to the effective use of record forms, Lucas said. A reviewing body should correlate the forms used by various programs and disciplines in the health department in order to avoid unnecessary multiplication, to assure consistency in format, and to make sure that the size of the forms conforms to that of the filing equipment in the department. Before introducing a new form into a records system, revising or combining existing forms or changing procedures should be considered.

Records Management

Office management implies the planning, organization, and control of office activities but in the health department the activities often control the office, Lucas stated.

Perhaps the greatest handicap to good records work is lack of interest in and support of good office methods and records management on the part of administrators, health officers, and program directors, Lucas asserted. Administrators frequently fail to make it clear to the staff that authority for certain operations has been delegated to the records clerk. They also sometimes allow

inefficient procedures to continue because they do not see the need for change and do not give authority to anyone else to make changes in routine procedures.

Although the records clerk has the principal responsibility for records, each member of the health department staff has some kind of records work to do. In local health departments, where the clerk's multiplicity of duties leaves insufficient time for records work, the burden of handling records falls on nurses and sanitarians, whose training and interests lie in other directions.

Filing is one of the most important areas in a records system, Lucas stated. Also, she pointed out, because of the many sources and types of information about each patient who comes to the attention of a health department, it is one of the areas of greatest confusion. To prevent misfiling and misplacing records, she suggested that one person be delegated to do all filing and refiling.

Lucas recommended unit filing by person, place, or family whenever possible. However, in large health departments, numerical systems have been found to be a satisfactory method. In departments which do not have a large volume of records, alphabetical systems are more practical.

Personnel and Training

Too few clerical personnel and employment of persons with insufficient skill and training in elementary office techniques hamper records work in health departments and make it necessary for other personnel to spend too high a proportion of their time on records, Lucas stated. Public health administrators have little training in the principles and practices of office management; physicians, nurses, and sanitarians are not expected to be competent in this field; and personnel with sufficient training are not attracted by the status or salary of the clerical position offered, she said.

There are practically no formal training courses for public health

records personnel, and inservice training courses provide little appreciation of the importance of integrating records with the work of the entire health department or of the significance of records procedures, Lucas reported.

Training courses for records personnel are urgently needed, she concluded. These courses should include instruction in office management, analysis of office methods, design and control of forms, filing methods and equipment, writing procedures, and coordination and utilization of data, she said.

Laboratory Activities Need Evaluation Aids

Properly prepared evaluation indexes help administrators measure the effectiveness of their programs and help win support for their budget requests, said Dr. Daniel Bergsma, New Jersey State Commissioner of Health.

The most potent evaluation procedure, he suggested, is a well-designed method of recording public health activities; for no program can be efficiently applied or evaluated unless it is recorded.

The evaluation indexes of the chemistry laboratory program of the New Jersey Department of Health covered scope, personnel, methodology, equipment, quarters, location, samples, and records. These indexes, according to Dr. Bergsma, were designed "to emphasize accomplishment rather than effort and to stress quality more than quantity."

Evaluating laboratory procedures, Bergsma said, must be viewed within the context of certain variables: the excess or lack of trained personnel in relation to the job to be done; the availability of adequate tools and facilities; the maintenance of balance between advanced training and new needs; and the preservation of balanced relationships with those who are served.

The criteria of these variables, he pointed out, might become com-

termine present and future needs; (b) organize new facilities or expand existing ones if supply will not meet expected demand; (c) utilize present and contemplated educational facilities to meet State and regional needs; and (d) promote an equitable distribution of dental personnel to serve an equal number of patients.

Nation's Dentist Shortage Estimated at 13,500

The number of dentists in the United States has become progressively *disproportionate to public* needs during the past 27 years, reported Dr. Quentin M. Smith, assistant chief, Division of Dental Resources, Public Health Service.

Within the same period, he added, the public's appreciation of good dental care, and the ability to afford it, have increased substantially.

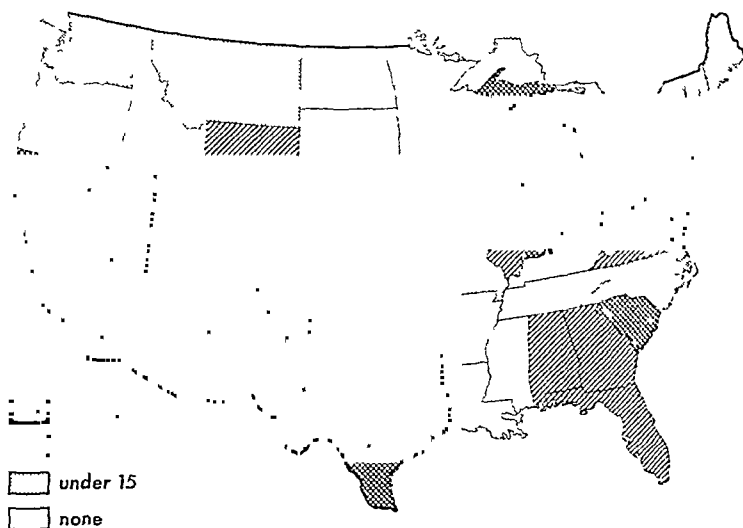

Estimating the current shortage of dentists in the United States at 13,500, with California and States in the Great Lakes and southwest regions showing acute shortages, Smith pointed out a need to expand dental training facilities if the Nation's oral health is to be protected.

Calculating Needs

In 1940, Smith reported, there was a ratio of \$2.2 million of personal income to every dentist; in 1955, there was one dentist to every \$4 million. Thus, "when before the war we had 2 dentists, today we have only 1 in relation to the same amount of purchasing power."

The fact that there is twice as much money available, however, does not necessarily mean that twice as many dentists could be used, Smith said, since competition for the consumer's dollar has increased. For this reason, in order to find a basis for calculating the need for dentists a 1955 average was taken of all States, creating thereby a hypothetical State having one dentist per \$4.3 million personal income. This value,

**Percent increase needed in dentist supply to meet demand level
of the top 24 States, 1955.**

after proper weighting by an index of population characteristics known to affect demand for dentists' services, was taken as representing an average level of "effective demand" for dentists.

An average of the 24 States having the largest number of dentists in relation to income (1 per \$3.6 million), weighted in the same manner, defined a second, more optimum level of effective demand. Using these two values as standards, Smith said dentist requirements at either level of effective demand can be calculated for any State or area for which information on income and population characteristics is available.

Taking into account all factors, "we would need about 6,000 additional dentists to provide every region with a dentist supply big enough to meet the demand level being met in the average State today, and it would take nearly 13,500 additional dentists to meet the demands equivalent to those being met in the top 24 States."

The regions needing the largest numbers of dentists are, in order, Great Lakes, far west, Middle Atlantic, and southwest (see map). In addition, one State located outside these regions—South Carolina—has a particularly urgent need for dentists.

Records and Measurements . . .

Improved Records Systems Seen Crucial Need

More than 40 years ago Dr. Charles V. Chapin of the Public Health Service pointed out that the absence of readily available facts was responsible for the lack of system in public health programs and

procedures. Yet today, reporting and recording systems are still inadequate, according to Nancy W. Lucas, supervisor, records consulting unit, division of vital statistics, Ohio Department of Health, Columbus.

Application of principles and techniques of office methods and records management to public health rec-

nant neoplasms, with special reference to cancer of the respiratory system, diabetes, all cardiovascular-renal diseases, influenza and pneumonia, and cirrhosis of the liver.

A questionnaire was sent to each physician who had signed a death certificate, asking for information on diagnostic methods and findings on which the certification of cause of death was based, an expression of his certainty of the diagnosis, and a revised diagnosis if his opinion had changed since he signed the death certificate. Questionnaires were also sent to the physicians, if any, who had attended the patient before the certifying physician. Coroners and medical examiners were also queried.

An internist directed the review of the questionnaires and original death certificates for type and amount of supporting diagnostic information, consistency between medical certification and diagnostic information, and the physician's expression of his certainty of the diagnosis. Both clinical and pathological information were considered. The reviewer's own impression of the certainty of diagnosis was added to the information obtained from the questionnaires and death certificates.

Diagnostic Information

Apparently most deaths are certified by the general practitioner rather than by the specialist, and, except for deaths from cardiovascular-renal diseases, relatively few deaths from the causes studied are certified by coroners or medical examiners. However, these deaths from cardiovascular-renal diseases can significantly affect the statistics.

The kind and amount of diagnostic information reported as being available to the physician certifying the cause of death varied considerably, from sketchy information in 38 percent of the deaths to good or very good information in 58 percent. The quality of reported information on diagnostic methods was best for malignant neoplasms; diagnostic information was "very good" for 68 percent of deaths from this cause.

For the other diseases studied, quality varied considerably with the cause of death.

The ratings of consistency between the medical certification and the reported diagnostic information indicated that for 79 percent of the deaths, the reported causes of death were the most probable diagnoses. For the medicolegal cases, however, the percentage was only 61 percent. In the 5 percent of deaths for which the certifying physician changed his diagnosis, the reviewer usually agreed with the new diagnosis.

The reviewer's scores of the amount and kind of information reported, the reasonableness of the physician's diagnosis, and the reviewer's own opinion of the accuracy of the diagnosis reported were combined and the diagnoses were grouped into four categories—"solidly established," "reasonable," "in doubt," and "probably wrong." Diagnoses were apparently solidly established in 43 percent of the cases, reasonable in 36 percent, doubtful in 10 percent, and probably wrong in 8 percent. Four percent could not be evaluated because of lack of information.

The proportion of solidly established diagnoses is higher for male than for female decedents and for persons under 75 years of age than for those who are older. The lower quality of diagnostic data in the older age groups may be due to the fact that attempts to make a definite diagnosis would not be helpful to the patient or it may be due to the uncertainty of the certifying physician or the reviewer as to which of several diseases caused the death.

Recommendations

Discussion of the significance of the data available from death certificates in clinical or clinical-pathological conferences of the principal disciplines associated with each case would be helpful in future studies, but this approach would be feasible only for deaths in a single institution. However, interviews by an internist with persons who have some knowledge of the medical as-

pects of the case might supplement the questionnaires.

Future Offers Statisticians Opportunity and Challenge

The statistical phases of nuclear energy programs, epidemiological studies of diseases, and planning and evaluating the resources, needs, and costs of health and medical services offer the statistician outstanding opportunities and great challenges, declared Dr. Ruth R. Puffer, chief, epidemiology and statistics section, Pan American Sanitary Bureau, Washington, D. C.

Health Statistics

In nuclear energy programs, the services of the statistician can be used in measuring radiation exposure and its effect on man, in determining permissible exposure to radiation, and in developing statistical methods for analyzing data on human and experimental population genetics, Puffer stated. Some long-range studies in this field might cover several generations, she said.

Throughout the health field, the statistician assists the epidemiologist and administrator by providing epidemiological data for use in studying diseases and health conditions. According to Puffer, clinical and epidemiological studies of the major causes of disability and death and of cardiovascular diseases, cancer, and mental diseases require that a statistician be a member of the study team.

On a world basis, differences between countries in terminology and classification of causes of death result in tremendous differences in death rates from specific causes and in other data, Puffer said. As an example of the need for understanding medical terminology as used in various languages, she cited the use of the term "toxicosis." In nearly all Spanish-speaking countries, "toxicosis" means a specific clinical entity resulting from severe and rapid dehydration from diarrheal diseases.

pletely subjective unless objective measuring tools can be devised and applied. This does not imply that evaluation teams must be used; he found from his own experience that self-evaluation achieves adequate objectivity without consuming the time of an evaluation team.

There is a need at present, Bergsma concluded, to find proper evaluation indexes to measure both quality and quantity of laboratory activities, and to find means of applying these indexes to State operated laboratories or those working under the approval of the State department of health.

Hospital Records Supply Information to Physicians

Much useful information, some of it of real value to the practicing physician, is available in hospital records, stated Dr. Robert C. Hoffmann, of the J. Hillis Miller Health Center, University of Florida, Gainesville, Fla.

However, although a great deal of information can be extracted from hospital records at reasonable cost by the use of mechanical devices, physicians need training and statistical guidance to enable them to use this information, Hoffmann declared.

Most practicing physicians make little use of hospital records, Hoffmann reported. They complete the records with effort, file them, and, except for clinical use of records of patients admitted to the hospital more than once, seldom use the records again. Perhaps this is because the information in hospital records is not easily accessible and few physicians have enough statistical training to appreciate the value of the information in them, Hoffmann suggested.

Potential Uses of Records

All physicians are interested in information which summarizes their own hospital practice and provides information with which they can compare their own practices and those of their colleagues, Hoffmann

said. Properly summarized records can give the physician a picture of the changes in the prevalence of hospitalization and in the incidence of disease and of the popularity of certain surgical procedures. In this connection, a practicing physician might ask his hospital for a periodic summary on his own patients and for summaries on all patients in the hospital.

The hospital record provides information on current practices and makes it possible to compare these practices with the results of research, Hoffmann pointed out. For example, in a recent study of records of patients hospitalized for coronary disease, it was found that treatment with anticoagulants had been given to only two-thirds of those who probably could have been benefited by this treatment.

Hospital records also make it possible for physicians to acquire information on a new treatment being used by their fellow practitioners. Hoffmann stated. A pool of information such as can be found in hospital records will increase the rapidity with which the effectiveness of the new treatment can be established. Hoffmann recommended that this use of hospital records be expanded. Furthermore, he said, in cooperative studies conducted in two or more hospitals, patients' records can provide data much more rapidly than can a study in a single hospital.

Hoffmann said that, with punch-card equipment and electronic machines for handling data, it is not difficult to abstract information from hospital records. The only limitations are the amount of information in the records and the amount of money spent.

Statistical Training of Physicians

Much more difficult than setting up an abstracting system is the problem of training physicians in the use of the abstracted information, Hoffmann stated. Such information cannot be used to the best advantage because many physicians are unfamiliar with statistical methodology, he said. However, since some

medical schools do not employ a statistician, in his opinion, few physicians can be expected to be familiar with statistical methods.

The responsibility for training physicians in basic statistics lies with statisticians and, as a professional group, they have done little to acquaint the members of other professions with the statistician's functions, Hoffmann stated.

In closing, he expressed concern about the role of the statistician in medicine and reported that a motion to seek joint meetings with medical organizations had been passed at the last meeting of the Eastern North American Region of the Biometric Society. Eventually, he said, a separate medical statistical organization probably should be established.

Study of Death Certificates Shows Diagnostic Difficulties

Complete and unfailing accuracy of antemortem diagnosis is unattainable, and insistence on absolute accuracy in the medical certification of causes of death is unreasonable. However, a study of diagnostic evidence available in support of recorded causes of death in Pennsylvania suggests that diagnostic data on which medical certifications are based are of a relatively high order of quality.

The study was conducted in cooperation with the Pennsylvania Department of Health for the purpose of determining the possibilities of developing measures of the quality of medical certifications of death and to ascertain the problems involved in the conduct of a study of this kind. The results were reported by Dr. Iwao Moriyama, of the National Office of Vital Statistics, and Dr. William S. Baum and William M. Haenszel, of the National Cancer Institute, Public Health Service.

The causes of death included in the study were tuberculosis, malign-

official health agency, or voluntary organization.

They also suggested, in reflection of low frequency reports for eye conditions and emotional disturbances, that visual screening be made part of health appraisal of school children and that physicians in the well-child conferences receive more intensive preservice and inservice training in mental health.

Another question raised was whether well-child conferences should set a definite policy on provision of treatment for skin, respiratory, allergy, nutritional, and gastrointestinal conditions, some of which are already being treated at the conferences. Such a plan, they reasoned, would integrate well-child supervision and treatment, eliminate delay in treatment, and lower the number of visits which a family has to make.

Study of the attendance pattern of the conference could stimulate further surveys, they said, offering a number of possible causes for the less than expected infant attendance and the dropoff after 36 months of age. Another field suggested for study was the preventive aspects of the most frequent mortality causes among postneonatal infants and preschool children—congenital malformation, accidents, and respiratory infections.

Early Prosthetics Stressed For Child Amputees

A prosthetic device applied at an early age becomes as much a part of the child as the shoe he wears, stated Dr. Carleton Dean, director of the Michigan Crippled Children's Commission. Child amputees who are nonwearers, he continued, run the danger of atrophy through disuse, contractures, ankylosis, or ancillary deformities.

Early fitting will lead the congenital and the traumatic amputee to his greatest potential of purposeful movements and motor patterns within the limitations of the prosthesis. For the congenital amputee

to achieve early developmental use, a medical evaluation and recommendation must be made during the first year of life, according to Dean.

Describing briefly Michigan's pioneer venture in child amputee services, Dean said that a preliminary survey of the State's child arm amputees revealed that 7 out of 8 were not wearing their prostheses, mainly because the devices were not functional. The commission then gleaned a register of child amputees from a list of crippled children in Michigan. In addition to determining caseload, this register assured accurate diagnostic evaluation and followup services, he said.

The pattern of the amputee program, as outlined by Dean, begins with examination of the child, evaluation, prescription, and therapy. Prosthesis fitting is followed by training, occupational therapy, and field service and clinical followup. Dean observed that results of training to overcome the physical handicap hinged largely on the degree of enthusiasm of the prosthetic team—orthopedists, therapists, nurses, prosthetists, and instructors. He attributed a large measure of the commission's success to the practice of followup supervision and guidance. Definite clinic appointments at regular intervals are made for the child's return visits, with postcard reminders sent out in advance each time. The reasons underlying broken appointments are investigated.

Dean made clear that child amputees from other States may be referred to the Michigan Area Amputee Center for treatment, by the appropriate official agency when such services are unavailable in the home State. The commission has received Federal funds to finance treatment of out-of-State child amputees.

Every State or area with a population of more than 2 million should have a child amputee center, but not more than one for each million persons, he said, since an insufficient number of patients will weaken the interest of the amputee team. He advised that such a center be set up in a city with a hospital or rehabili-

tation institution having such specialists as a pediatrician, internist, plastic surgeon, urologist, a physical and an occupational therapist, and a medical social worker. The limb shop would ideally be in or near the hospital and directed by a certified prosthetist.

Dean mentioned available courses for prosthetists at the University of California at Los Angeles and at New York University. For study of the management of child amputees, he announced that orthopedic surgeons and physical and occupational therapists may enroll in courses at the Michigan Area Amputee Center in Grand Rapids.

Breast Feeding Variations Reported in New York

The practice of breast feeding of infants is more common among higher than lower socioeconomic groups, according to a survey of 1,433 upstate New York mothers who had given birth under normal conditions 3 to 6 months before.

The project, which studied variations in childbearing and child-rearing health practices according to social class, was reported by Dr. Alfred Yankauer, director, bureau of maternal and child health, New York State Department of Health, Dr. Walter E. Boek, research anthropologist of the same department, and Dr. Edwin D. Lawson, assistant professor of psychology, State University of New York College for Teachers, Albany, N. Y.

Interviews were carried out by 490 specially trained college students in social science and nursing in 15 widely scattered rural areas, villages, and cities near the participating schools. Although the selected sample represented from 1 to 36 percent of the number of annual births in these areas, it was by chance similar in many ways to the universe of families having births in upstate New York. The authors pointed out, however, that representation from central cities was heavy and suburban areas were unrepresented.

The International List of Diseases and Causes of Death assigns toxicosis in children under 1 year of age to "ill-defined diseases peculiar to early infancy." In Chile, assigning toxicosis to "diseases of early infancy" has resulted in high death rates from these diseases and low death rates from diarrheal diseases in infancy, Puffer stated.

Health Services

Puffer said that definitions and standards are needed in planning health and medical services and that the experience of statisticians concerned with morbidity studies, prepayment insurance programs, hospital statistics, and other phases of medical services is valuable in establishing national and international standards. She stressed the importance of the development of comparable statistical data on a world basis so that comparisons can be made of data in areas with varying environmental conditions.

Quality Control Urged For Mortality Data

Before mortality data can be accurately used for epidemiological research, a means of measuring the biases of the data must be developed, according to Dr. Tom Donnelly, School of Public Health, University of North Carolina.

"Epidemiology," he said, "has reached the state where the analytical tools it uses are more powerful than the accuracy of its raw data would warrant, at least when these raw data come from published vital statistics."

Donnelly, pointing up analytical difficulties involved with mortality data on heart disease, said that almost all measurable social factors are associated with heart disease. But no single measurement can describe the separate effect of any factor because each factor interacts in its own particular way with the others. With so many factors operating, it is possible to "prove" any-

thing, Donnelly said, merely by selecting some factors and ignoring others.

Conclusions derived in this manner contain what might be called analytical biases. More basic, Donnelly said, are the statistical biases inherent in the mortality data. Biases or errors may occur from an improper classification of a disease resulting in under- or over-estimation of mortality, or they may occur from additions to or omissions from the bookkeeping system after the patient has died. In either case, no quality control system exists, Don-

nelly said, which can determine the magnitude of biases or errors in mortality data.

Donnelly urged that steps be taken to measure this magnitude. As the initial step, he suggested listing procedural aspects of collecting vital statistics that are subject to biases or errors, so that the cost of either measuring accurately or reducing errors and biases may be assessed.

It is not necessary, he emphasized, to eliminate biases; one need only measure them. Once they are measured, the statistician will be able to do accurate factorial analyses.

Maternal and Child Health . . .

Recommend Screening Child For Eye and Mental Health

Among 950 presumably well infants and preschool children examined in Minneapolis well-child conferences of 1957, about 37 percent were found to have at least one health problem, according to a study reported by Dr. Helen M. Wallace, Dr. Evelyn Hartman, Vernon Weckworth, and Dr. Eunice Davis of the University of Minnesota School of Public Health and the Minneapolis Health Department.

Studied by the University of Minnesota School of Public Health and the Minneapolis Health Department in April, and again through June and July, the conferences showed that the highest frequency of health problems occurred in children 49 to 60 months of age, in nonwhites, and in boys. In general, infants and younger preschool children had a lower frequency than the older preschool group.

The authors also found that 29 percent of the children had 1 health problem, 6.7 percent had 2, and 0.6 percent had 3. The most common conditions identified were skin and respiratory, with cardiovascular, orthopedic, genitourinary, allergy,

and nutritional problems appearing next in frequency; followed by eye, gastrointestinal, and ear conditions. Low percentages were reported for both dental and emotional irregularities, which the authors attributed to possible lack of interest of examining physicians. Individual conditions occurring most frequently were respiratory infection, diaper rash and other skin disturbances, and umbilical hernia.

Eight percent of the children had had an accident since the last visit, the greatest frequency occurring in age groups 13 to 20 months and 25 to 36 months, and among whites. Falls caused 69 percent of the mishaps, and burns and ingestion, 10.7 and 4.8, respectively.

Translating these data into indexes of community needs, the authors recommended that, for such common health conditions in infants and preschool children as cardiovascular, orthopedic, genitourinary, eye, and ear problems, diagnostic and treatment speciality services be set up. They added that the group responsible for child health supervision must accept some responsibility for spurring development of these services, whether in the official crippled children's agency, teaching hospital,

offers considerable guidance in teaching how to organize a school health program, he said. Many practical points emerge, for example, in the cooperative planning that helps the school complement, rather than interfere with, the family-physician relationship. By participating in such planning, Lichty noted, future physicians can learn while they perform a local service. Denver physicians in charge of school health present cases at the medical school each year.

To show the effectiveness of routine active immunization of children, the university pediatrics department compares the morbidity and mortality statistics on diphtheria and pertussis of the State before and after such immunization. Among other teaching material, Lichty mentioned a study showing the need for more cooperation of physicians and parents in immunizing infants, a study of heart disease in Colorado's sixth-grade school children, and another of the State's mortality from appendicitis.

According to Lichty, a prime teaching benefit derives from Colorado's premature infant service. The department sends premature infants directly to the university hospital and pays for a large part of their care.

Health department personnel are in constant touch with developments in the supervision of the newborn nursery of the university hospital, a contact reflected in the department's official plans and rules for nursery operations. Routine inspections of community hospitals are rather guidance sessions than "police actions," he said. Often, department officials suggest that medical school professors give short refresher courses in community hospitals to clear up trouble spots.

Lichty believes that leaders of State and county medical societies are more prone to approve public health suggestions that have the support of a responsible university faculty member.

Any public health activity for children can benefit from this dual

function, Lichty said, adding that the consultant himself, through constant intellectual bombardment, derives the greatest personal benefit.

Custom-Made Plans Urged For Developing Areas

"Only the scientific principles of Western public health practice are universally applicable, not program patterns," stated Dr. Jessie M. Bierman of the School of Public Health, University of California, in a review of World Health Organization-United Nations Children's Fund activities in maternal and child health in developing countries. Prefabricated Western-type programs need re-orienting toward local needs and resources, she said.

Epidemiological methods from the West, however, as well as the problem-centered approach can be transferred to these areas. In this connection, Bierman emphasized the need for more local morbidity and mortality data and for studies of the growth and development patterns of children, feeding practices, and beliefs and traditions concerning childbearing and child rearing. She also recommended study of the influence of socioeconomic and cultural factors

on the patterns of disease and on the workability of health measures, noting that most health problems in underdeveloped areas stem, rather than from exotic tropical diseases, from inadequate sewerage systems, squalid, overcrowded housing, and contaminated, meager water supplies.

The scope of maternal and child health programs needs broadening, she said, to embrace general health needs of mothers as well as special needs centering on reproductive and growth processes.

Bierman took issue with the current concentration of child services on the neonate at the expense of the older infant and young child, since major health problems in developing areas—undernutrition, malnutrition, and intestinal infections—begin during weaning and continue through the second and third years of life. She pointed out that some countries report about as many early childhood deaths as infant deaths.

During 1947-56, Bierman said, 601 WHO fellowships enabled maternal and child health workers to pursue training abroad, and through UNICEF-WHO assistance, governments set up, extended, or improved their personnel training facilities. She reported good progress in general in training personnel and in the extension of minimal services.

Manpower . . .

Health Manpower Challenge Tackled on Broad Front

Manpower for health work hinges most of all on how realistically the health profession meets the challenge of competition for labor in the face of a limited supply of skilled young workers, said Dr. Leonard A. Scheele, former Surgeon General of the Public Health Service, speaking as chairman of the Commission on Health Careers, National Health Council.

The commission was organized recently as an outgrowth of the Health Careers Project of the council, launched to support career development and recruitment for the profession.

Reviewing some of the accomplishments of the Health Careers Project, Scheele mentioned that it has highlighted the gaps in information on health manpower needs and in the health profession's plans to meet competition for labor. The project has also shown that such competition means more than recruitment, that

For classifying into social groups, the Warner Index of Social Characteristics was used together with photographic guides to characterization of house type and dwelling area. The index, they explained, is based on the sum of scores for occupation, income source, house type, and dwelling area, weighted in the order given.

Other survey results mentioned were:

- One mother out of every three worked during her most recent pregnancy, with roughly the same distribution in each class.

- Among mothers in social class V (lowest), 26 percent had not sought postnatal care at the time of the interview, compared with 13 percent for all mothers.

- One out of four mothers had ever received breast feeding. It was most popular and was continued longest by social class I and II mothers, while the reverse was true of those in social class V.

They urged health authorities to consider drawing on the interest and manpower of college and university social science departments, pointing to the mutual benefits of experience and data from their projects.

Such a survey can measure the extent to which observed health practices meet generally recommended standards, they stated, adding that social class groupings may pinpoint one class as a program target, as in this study, in the question of postnatal care, and the distribution of specialist services.

Since the survey can be duplicated later, it can be used to evaluate the effectiveness of a public health program and measure progress in health practices, both generally and by class. A further suggestion was that, through this technique, health departments expand their function of morbidity and mortality reporting to include health practices and knowledge. Probing desired and expected health services of the community was another recommendation.

The authors concluded with the thought that measurements them-

selves have unpredictable values. Therefore, possible shifts in such factors as social class patterns of breast feeding of infants may have more meaning 10 years hence.

Navajo Child Health Level Mirrors Tribe Future

On the principle that the health of the school child is the key to the general health level of the community, Dr. John C. Cobb, of the Division of Indian Health, Public Health Service, Albuquerque, N. Mex., says that one may determine the design of public health activities and forecast the lines of tribal social and economic growth among the Navajos.

Health Record

Infant mortality is about 99 per 1,000 live births among the Navajos, a tribe of more than 80,000, living in widely scattered, small and crowded hogans. This rate, said Cobb, mirrors the fact that, for many Navajo mothers in labor, reaching the hospital means a wagon trip over more than 50 miles of sandtrack.

More than a third of Navajo school children so far examined have signs of active or healed trachoma. About a third are tuberculin positive on school entrance, one-half testing positive by age 16. The tuberculosis case rate is more than 600 per 100,000 population, Cobb remarked. Between 5 and 10 percent of the school children have chronic draining otitis media or perforated eardrums, with partial deafness. School children compose one-third of the total Navajo population.

As a background for this health record, Cobb recalled that the Navajos have contended with limited resources on the reservation, drought, a ban on sheep grazing to stem erosion, and lack of water, combined with a tenfold growth in population in less than 90 years.

School Child Health Index

Those planning public health activities for the Navajo tribe face

the challenge of doubtful statistics, Cobb said. Cultural taboos against mention of death, for example, and recording in overcrowded clinics hinder accurate reporting. Statistics for the large school population, on the other hand, are readily accessible. Cobb proposed setting up an index of the percentage of children in a selected grade who are in good health. This, in effect, is a yardstick for measuring the end results of maternal and child health programs. He then submitted a list of conditions tentatively defining the child's good health.

Cobb believes that, in addition to local uses for the index, it can be used to compare the health of school children in various parts of the world and can pinpoint the targets for technical assistance in public health.

Pediatric Professor's Own Mutual Aid Program

The advantages of having an associate professor of pediatrics serve as pediatric consultant in a State health agency were described by Dr. John A. Lichty of the University of Colorado Medical School, who has received such an assignment with the Colorado State Department of Public Health.

University pediatric departments, Lichty said, can consider public health questions in hospital nurseries, communities, or in the entire State to be like individual clinical cases in the instruction of medical students. As in clinical medicine, he pointed out, the use of actual cases sharpens the effect of teaching.

Illustrating the public or community case, Lichty cited results of a neonatal mortality study in Colorado. The survey effectively demonstrated to the students the importance of improving care of the newborn and provided substance for discussions of possible factors in neonatal mortality.

Experience in a health department, in contrast to pediatric textbooks,

planning to practice their profession, rather than go into research or teaching, is limited.

The Public Health Service, which among the Federal agencies has the major concern for sanitary engineering and related professional personnel, offers the following educational support in this field:

1. Research fellowships authorized by title III of the Public Health Service Act of 1944 were extended to sanitary engineering in 1957. They are aimed at increasing the number of engineers and scientists qualified to conduct independent research in problems of environmental sanitation.

2. Traineeships awarded under title I of the Health Amendments Act of 1956 are available to sanitary engineers, sanitarians, sanitary chemists, and allied personnel. These are intended primarily to bring new people into public health and thus give preference to persons who are under 35 years of age and who have had no more than 2 years' experience in public health and less than 1 year of graduate or specialized public health training.

3. Training grants-in-aid for study in air pollution control originate under the Air Pollution Research and Technical Assistance Act of 1955. Recipients are of three types: individuals, State and local government agencies, and educational and training institutions.

Recommendations of the Conference on the Education, Training, and Utilization of Sanitary Engineers held in the spring of 1957 indicate recognition of the need for increased financial aid, according to Butrico. This conference, he reported, recommended (a) that graduate fellowships and traineeships be expanded and that they carry no restrictions on the duration of training award to any qualified individual including the doctoral candidate and (b) that financial assistance be extended to undergraduate education of engineers and that a monthly stipend of not less than \$100 plus allowance for tuition and books be provided.

Butrico gave the following reasons for his contention that "much more assistance" for graduate students interested in environmental health is necessary: increasingly complex public health problems; general up-grading of health activities; the expectation that broad education will precede specialization; the need for increased competence in all sanitation personnel, including the sanitarian; the need for an "impressive battery of specialists trained in disciplines not necessarily a part of engineering," such as biologists, physicists, chemists, bacteriologists, and meteorologists; and the low starting and maximum salaries for an engineer in public service in comparison with those in industry.

Considering the question of financial assistance for higher education in general, Butrico observed that only 556 of the 58,000 students applying to the National Merit Scholarship Corporation in the first year of its operation (1955-56) received scholarships.

He also pointed out that a study by C. C. Cole, Jr., sponsored by the National Science Foundation, reported that insufficient financial resources appear to be the sole or primary reason why 60,000 to 100,000 persons of superior ability fail to enroll in colleges each year. The Educational Testing Service, he added, has estimated that some 150,000 high-ability students would have gone to college had adequate financial support been offered them.

Measures Nursing Needs Outside Hospitals

A new method of estimating the number of nurses needed by a community was described by Janice E. Mickey, associate professor of public health practice (nursing), Graduate School of Public Health, University of Pittsburgh. A study is being made of the basic nursing needs of the general population of Butler County, Pa., in order to determine how many public health nurses,

school nurses, and occupational health nurses are needed in the county.

The Study Sample

Families selected at random are interviewed by a nurse, who decides whether the family has health problems that might be helped by the services of a public health nurse, Mickey stated. The sample studied is large enough for generalizations to be made from the data and for an estimate of the extrahospital nursing needs of the population of the county.

To check the reliability of the estimate and to determine whether the single interview misses important problems that can be discovered only with intensive home care, county health department nurses give nursing care to all families considered by the interviewer to need such care, and certain families who were judged by the interviewer not to need nursing care are referred to the health department, Mickey said.

It is thought that referrals to the health department are influenced by the nurse's background and her concept of public health nursing. However, a check of estimates of need for nursing care by two nurses visiting the same 20 families showed a gratifying consistency in results of interviews, Mickey reported. Estimates of the need for care were more consistent than measurement of the family's ability to cope with a situation, she said.

The sampling process is complex and it is often difficult to locate and reach the households, Mickey stated. Interviews vary in length from 35 minutes to 2 hours, averaging an hour and 10 minutes. Nurses average a little over 1½ completed schedules per day in the early part of the study.

To see how effective the nursing service has been, a subsample of families is interviewed a second time. Families referred to the health department are reinterviewed after the public health nurse has closed the case; families receiving nursing care are reinterviewed at the end of 3 months.

facilities, teachers, and earning opportunities may affect the interest of youth in health careers, and that such questions need study. Scheele also gave the project credit for opening the door to new and effective allies and, above all, for demonstrating that effective action must come from nongovernmental sources.

Scheele described the commission's five-pronged range of interest:

- The current and expected supply and shortages of health personnel; as well as the possibility of tapping other manpower sources.

- Utilization of personnel, including assessment of the health field's competitive position in recruitment.

- Job satisfaction, which includes earnings, fringe benefits, and opportunities for advancement, emphasizing solid facts rather than assumptions.

- Education and training for occupations in health, considering the impact of the school shortage on professional education; as well as new types of training for supporting occupations.

- Recruiting, with emphasis on evaluation of new methods and materials in communication techniques.

Scheele said that the most urgent questions which are open to prompt but lasting solution will be identified chiefly through factfinding and research, drawing on all accessible sources of information. In turn, the facts will be made available to all professional and voluntary associations, operating agencies, and educational institutions, to bolster their efforts in staffing health services.

He underscored the fact that the commission will take direct action, through the mediums of public information and education, to underpin efforts in training the Nation's youth in health fields.

Trained Records Personnel Major Necessity

Qualified workers are a first requirement of health department

record systems today, and only specialized training will provide such personnel, declared Alpha K. Kenny, formerly consultant in records training, Communicable Disease Center, Public Health Service, Atlanta, Ga.

Records, the mirrors of services, should reflect today's ideas, methods, and devices, Kenny stated. To accomplish this, trained supervisors are needed to manage records departments and to train staffs, she said.

The Public Health Conference on Records and Statistics, sponsored by the Public Health Service and the Association of State and Territorial Health Officers, has focused attention on the need for improvement in public health records and their management, Kenny stated. In addition, the nursing section of the Southern Branch, American Public Health Association, has promoted interest in records among nursing schools and field teaching agencies in the southern States, and the National Health Council, through its Health Careers Guidebook, has stimulated the interest of college students in public health records.

Training Opportunities

In 1953 the department of field training, University of North Carolina School of Public Health, the W. K. Kellogg Foundation, and the Public Health Service sponsored a working conference on the training of public health records personnel. In April 1957 the University of North Carolina School of Public Health and the Training Branch of the Communicable Disease Center, Public Health Service, offered a 2-week course on management of public health records. Twenty-six record analysts from 13 States and 6 Public Health Service units attended this course at Chapel Hill, N. C., Kenny reported.

A number of States offer opportunities for training to local public health records workers, and other States are planning similar courses, Kenny stated. The departments of health administration in two schools

of public health have held seminars on records management, and forms design has been included in their courses in public health statistics, she said.

Future Training Needs

Employers and merit systems have a joint responsibility for encouraging and helping employees to qualify for the more advanced positions in records management, Kenny asserted. She recommended that merit system authorities set up positions that will attract and hold competent people and that employees in the lower classifications be given inservice training that will qualify them for more advanced positions.

More than inservice training, short courses, institutes, and workshops is needed, however, to prepare personnel for advanced positions in public health records management, Kenny said. She suggested that undergraduate work in public health administration include courses in records management, and that graduate work be provided for students who can qualify for such programs.

Field demonstrations of public health records systems would be a helpful supplement to formal academic courses, Kenny concluded. Held in strategic locations, they would give students an opportunity to see records systems in actual use, she said.

Increased Financial Support Urged for Health Training

A plea for increased financial assistance for training in environmental health was voiced by Frank A. Butrico, chief of the Engineering Resources Program, Public Health Service.

Reviewing current grant and traineeship offerings, both inside and outside the Federal Government, he observed two major deficiencies: there is virtually no undergraduate assistance specifically for persons interested in a public health career; assistance for graduate students

as "Golden Age" or "Senior Citizens" clubs, Kutner said. It is in such clubs as these that they may learn about their specialized needs and how to meet them.

Kutner warned against mere exhortation as inducement to people to take action and said that, if exhortation is to succeed, the situation must be made meaningful to the individual, centering specifically on his personal situation.

Program Elements

As to the elements of a successful program for senior citizens, Kutner said:

1. Make the programs specific and thereby induce groups of older people to establish regular health habits. In groups, there is a tendency for each person to be influenced by the desires and wishes of the others.

2. Bring groups of older persons to various centers to see for themselves.

3. Keep the older person apprised of health education activities (radio and television programs, books, pamphlets, speakers).

4. Establish an up-to-date directory of health services available to older persons and provide at least one responsible individual who can make appropriate referrals to a health agency.

5. Make mental health an integral part of the program. The very programs the center creates are themselves aspects of the mental health education program.

Current Techniques

Kutner gave examples of programs throughout the country in illustration of techniques currently in practice.

The Marin County (Calif.) Senior Association purchases and prepares gifts to be distributed at hospitals by Red Cross Gray Ladies.

The New Hampshire Golden Agers assist the mental hygiene and child guidance clinic by sending birthday cards and letters to children under the care of the clinic.

The Amalgamated Clothing Workers of America, with one center in Philadelphia and one in New York, stresses the relationship between leisure-time activities, social adjustment, and the maintenance of health.

The Akron (Ohio) Golden Age Club prepares, for the General Hospital, medical records for microfilming or for mailing.

Senior Achievement Incorporated (Chicago) employs about 25 workers in the production of such items as wooden footstools, cradles, and sandals as well as in clerical and drafting jobs.

Meaningful Activities

Government and voluntary agencies have programs based upon the concept that physical well-being and sound mental health are enhanced by activities which offer an oppor-

tunity to the individual to contribute in some meaningful way to the community at large or which provides sources of additional income. He mentioned the Minnesota Department of Health, the Sirovich Center (New York City), the Ithaca (N. Y.) Senior Citizens' Center, the Women's Education and Industrial Union (Boston), and the Sunset Industries (Bangor, Maine), as outstanding examples.

In conclusion, Kutner pointed to the Pasadena-Altadena Committee on Aging, the Greater Muskegon Geriatric Council, and other agencies both public and private. These centers are training leaders for dealing with the aged. Such programs of leadership training and activities for the aged, and the wealth of health education materials indicate the scale on which the efforts for the aging are progressing.

Medical Care . . .

Home Care Programs Extend Hospital Care

The establishment of home care programs by general hospitals and use of the facilities of these programs by physicians for their private patients is proving to be a major and highly desirable development in medical practice.

This belief was expressed by Dr. Peter Rogatz, associate director, division of professional services, Health Insurance Plan of Greater New York, and Guido M. Crocetti, acting director of research and planning, New York City Community Mental Health Board, in their discussion of the impact of home care programs on the place of the hospital in medical care.

Service to the Community

New concepts of medical services to be provided by hospitals include home care programs which use teams of physicians and other professional

personnel to care for homebound patients who do not require hospitalization but who cannot be cared for in outpatient clinics. The growth of these programs is an indication of the hospital's development as the center of community health and medical services.

Most home care programs provide medical care to medically indigent or indigent patients by hospital residents, other salaried physicians, or practitioners in the community who devote only part of their time to the home care program. However, home care can be extended to self-supporting patients of private physicians without interfering with their professional and financial relationships, and provision of services to these patients will reduce the need for subsidizing home care programs.

Home care is a qualitative addition to community health services rather than a means of saving money or hospital beds. Caring for patients at home does not release an equivalent

The Interview Schedule

The interview schedule includes questions designed to obtain data on needs for bedside nursing care and treatment for acute and long-term illness, prehospital and post-hospital care, rehabilitation, and diagnostic services, as well as data on practice, skills, knowledge, and attitudes in relation to home care of the sick and ability to recognize illness, family health practices, and family health protection, including periodic health appraisal and immunizations.

The schedule was tested on a group of families with various health prob-

lems, and after analysis of the findings and some revision of the schedule, it was set up for coding. Although a small part must be completed by a coder, the schedule is for the most part self-coding.

The cooperation of the families interviewed has been excellent, and the entire community has supported the study, Mickey reported. The health department assisted with the basic plans; the board of health made it possible to obtain the approval of the medical society; and newspapers and radio stations paved the way for the interviewers who went into the homes.

The annual report of his department was first presented over station WHO-TV, Tuesday, February 1, 1955, from 1:30 to 2:00 p. m. In telling the group how to do it, he said, "First consider what you wish to accomplish."

Each section of the department submits monthly records from which annual reports are compiled.

To communicate the health department story, the program utilized role playing, problem-solving situations, conferences, cartoons, photographs, demonstrations, and charts. Christensen rewrote the material and fitted it to the allotted 30 minutes. Each section rehearsed its portion of the script separately. The entire department cast (15 members) rehearsed twice prior to the dry run at the TV station.

The telecast, besides department personnel, consisted of the chairman of the board of health, the city manager, the executive secretary of the Council of Social Agencies, and 14 others, including a mother and baby. In answer to the request for permission to televise the next year's report, the station manager asserted, "On one condition: It must be at least half as good as last year's report."

Golden Age Clubs Educate For Healthful Living

Some older people of their own accord obtain information and engage in activities which help them maintain health. For such people, Dr. Bernard Kutner, of the Albert Einstein College of Medicine, thinks special education programs are largely unnecessary. For others, they are highly necessary.

Although many physicians do not regard geriatric problems as a "specialty," they recognize the need to give specialized attention to the health problems of the aged.

An increasingly large number of people are enrolling in programs of adult education, recreation, leisure-time classes, and in clubs referred to

Education . . .

Communication's "Why?" Is All Important

Each health organization must improve its internal communications before it can expect to communicate successfully with its clients in the community, stated Chester S. Bowers, director of the bureau of public health education, Connecticut State Department of Health.

Bowers defined internal communication as "meaning and including all workers within an organization," and not exclusively professional and quasi-professional personnel. Communication even within a single organization, he said, is not substantially unlike problems, and ways to their solution, met in health education of the public.

Communication's "Why?" is more important than its "How?" Bowers said. He put the chief emphasis on persons concerned rather than on the medium or the material. The expert should be on tap and not on top, he told his listeners. No one, not even an expert, can give appropriate answers until given the questions. A symbol for effective communication may be thought of as a roundtable at which people are relating themselves to each other, he said. In

a network of mutuality, the lines of communication are down less frequently, and the messages are less likely to be misheard or misread.

He said, "The administrator or the officer and field practitioner within an organization today who looks upon communication simply as a matter of issuing a directive or statement of information is open to disappointment in the response elicited. Quite frequently these are the same individuals who fail to achieve the results they expect from health education programs they administer or at which they practice. Conversely, the administrator and practitioner with habitual willingness to permit careful and considered observation of each situation . . . is the more likely to gain the response and objective anticipated."

Annual Reports Recipe: Televising Them

The values of presenting a health department report through television were extolled by Sophus R. Christensen, director of public health education, Des Moines-Polk County Department of Public Health.

Disadvantages

With their offices at the hospital, physicians lose some fees because they no longer perform minor laboratory tests in the office, Rorem stated. Some hospital staff members who do not have offices at the hospital feel that the physicians who do have offices there are more likely to be called to treat staff service cases in an emergency. And relatives of hospital patients sometimes pay time-consuming visits to their physician to discuss members of their families.

Rorem pointed out that patients will go any distance for inpatient hospital service but they feel that their physician's office should be conveniently located, and if it is not they may not make office visits regularly.

Costs of renovation or construction and difficulties in assigning space when there are more staff members than offices have sometimes deterred hospitals from establishing private office facilities, Rorem stated.

In conclusion, Rorem said that locating physicians' offices in or adjacent to hospitals is an effective use of capital and coordinates professional services. The potential public health value of such an arrangement is great, and it will probably be more fully realized in the future.

Government Must Study Medical Care Needs

The chief need of health agencies is to learn more about the quality and comprehensiveness of medical care, including how patients seek care, reasons for discontinuation and overlapping of services, what services people want, and the reaction of patients to the care they receive, in the judgment of Dr. Leona Baumgartner, commissioner of health, New York City, and Margaret Klem, medical economist, Public Health Service.

With the rapid growth of voluntary health insurance, the development of inplant health units or union health centers in industrial areas,

the increase in services offered by medical societies, fraternal organizations, and some religious groups, and the expansion of agencies dealing with specific diseases, the public is becoming increasingly interested in both preventive and curative health services and is demanding more and better medical care, they said.

Although cost is a factor in a patient's decision to seek medical care, his cultural background, his education, and his own or his neighbor's experience may be as important influences on his knowledge and attitudes toward medical care as is his economic status, they believe.

However, regardless of how the cost is met, no comprehensive picture of the use of health and medical care services is possible without knowledge of the kinds and sources of professional care received, they assert. It is equally important, they add, to know, for example, the relationships among agencies, between agencies and physicians, and between the patient and each person or agency who provides medical care, in order to determine what relationships are desirable and what should and can be done to improve existing relationships.

A study of health and medical care services by the New York City Health Department seeks to discover the kinds of medical services families receive from voluntary health insurance agencies, to find out why patients go from one source of medical care to another and what pattern of change they follow, and to ascertain their reactions to the care received. These data may also reveal gaps or duplications in services provided by various agencies.

It is hoped by Baumgartner and Klem that this study will reveal factors that either impede or promote effective use of health services and ways in which the administration of medical care services can be geared to community needs and demands. The results may indicate the need for a continuing program that will keep practicing physicians informed of both existing and new

activities and of the extent to which various health agencies serve as case-finding agencies as well as co-ordinators of medical services.

The study, they feel, is sure to point out certain ways of improving specific local health services. It is an example of one of many kinds of studies they believe are fundamental to a better understanding of problems of providing medical care in this country.

Joint studies by health personnel and social scientists and the efforts of public health departments, medical groups, and universities are needed, they say, if health and medical care services are to be the best that medicine can offer.

Windsor's Medical Plan Termed a Success

About 85 percent of the residents of Windsor, Canada, participate in Windsor Medical Service, a voluntary, comprehensive prepayment plan which provides medical services at home or in the physician's office, and surgical, obstetrical, and special services, X-ray and laboratory services, and hospital care to its subscribers on a fee-for-service basis.

The results of a 3-year study of the Windsor Medical Service plan were reported by Benjamin J. Darsky, Dr. Nathan Sinai, and Dr. Solomon Axelrod, of the bureau of public health economics, School of Public Health, University of Michigan, Ann Arbor. Their investigation of Windsor's 20-year experience with the plan indicated that comprehensive physician's care insurance is needed, is not used unreasonably, and is paid for willingly in that city. Results of the study also suggested that the reasons usually given for limiting physicians' services in prepayment plans are not valid.

Principal Issues

Because the cost of individual home or office visits is usually modest, it has been said that insurance should cover only surgery or hospitalized illness. Although most in-

number of hospital beds but it does take care of long-term patients who could not be given hospital care for extended periods.

Personnel

Experience in the home care of patients should be part of the training of medical, nursing, and social work students. Such experience should prepare them to understand and cope with the social and economic aspects of illness and should increase their appreciation of the hospital as a community agency. This understanding and appreciation will be reflected in their future attitude as practicing physicians, nurses, or social workers.

Employment of full-time physicians in home care programs has not proved satisfactory since most programs cannot offer salaries that will attract competent physicians. Employment of practicing physicians part time, either on a salary or fee-for-service basis, is more apt to attract well-trained practitioners.

Physicians who have served in the program will be influenced in their future interests and skills, and representatives serving on the board of directors of voluntary nursing agencies will be enabled to use the agency's home care experience in policy making.

Because of the widespread shortage of nurses and the experience of nursing agencies in providing home nursing service, home care programs usually use the services of existing nursing agencies. However, the quality of nursing care received by the patients will be directly affected by the skills of the physicians and the policies and procedures of the home care program.

Physicians' Private Offices In Hospitals Increasing

Medical staffs and hospitals are being brought into closer relationship through the establishment of private offices in hospitals or in connecting buildings, reported Dr. C.

Rufus Rorem, executive director of the Hospital Council of Philadelphia. The council, through a grant from the Public Health Service, is making a study of private office practice at institutions where physicians are carrying on individual practices, Rorem said.

Most of these facilities for physicians' private offices are owned by the hospitals, Rorem stated. Rents are comparable to those in other office buildings in the community. Occupancy is usually limited to active members of the hospital staff, with priority based on rank or length of service. Physicians occupy contiguous offices, share certain overhead expenses, and are available to each other for consultation and for referring of private patients.

Some income-sharing groups of physicians have rented space in hospital office facilities, Rorem said, but the development of such facilities apparently has not of itself inspired the formation of groups for private medical practice. However, it has acquainted many physicians with the advantages of practicing close to other physicians and of the accessibility of the equipment of a modern hospital.

The principal reasons for establishing physicians' offices at hospitals have been convenience, saving of time, and increased use of hospitals, Rorem said. Other reasons have been change of hospital location and changes in zoning laws.

Legal Considerations

Physicians' private offices are considered to be private business activities of the hospital and the capital investment has been subjected to real estate taxes in some jurisdictions, but the income received from them has not been subject to Federal income tax, Rorem stated. Use of endowment funds for the construction of office facilities at hospitals is legal, provided that the income is comparable to the income that could be expected from other investments, he said.

Government tax funds have not

been used directly for the construction of office facilities at hospitals, although some "Hill-Burton" hospitals have included such offices. Local banks have loaned funds for this purpose, according to Rorem. No public campaigns for funds for office facilities have been held as far as he knows.

Advantages

Physicians who maintain offices at hospitals agree that this arrangement enables them to practice better medicine with less expenditure of time and energy, to have more personal contact with inpatients, and to make hospital rounds more often, Rorem said. Other advantages are the saving of transportation time between office and hospital, the ease of referring patients to fellow staff members, and the fact that in an emergency hospital patients can be seen without major interference with office appointments. One physician reported that he orders private-duty nurses less frequently since he is easily accessible in an emergency, Rorem reported. Hospital diagnostic facilities are easily available, and patients who become used to visiting the hospital for office calls are less resistant to hospitalization, physicians find.

Patients find that the physician who maintains his office at the hospital is usually in or easily available, and office appointments are not canceled because of hospital emergencies, Rorem stated. They also find it convenient to consult other hospital staff members to whom they are referred and to visit hospital departments for diagnostic and treatment services.

In the opinion of hospital trustees and administrators, location of physicians' offices at hospitals has resulted in a feeling of unity between the institution and the medical staff, Rorem reported. Physicians learn about hospital costs, can observe the critical phases of recovery of their patients, and become familiar with the duties performed by other members of the hospital staff.

Efforts have been made to attract physicians to rural areas, but none have been really successful, he said.

In Latin-American countries, state-financed public health services are responsible for health services to the entire population, Bravo stated. Local health units give preventive services to individuals, but the need for curative treatment is so pressing that these local units are devoting more and more time to this service, he said. Maternal, child, and school health services are part of the local health activities. Government-sponsored hospitals and clinics give free care to the medically indigent as well as to paying patients.

All Latin-American countries provide sickness insurance which gives varying amounts of care to ambulatory patients, Bravo reported. This insurance is usually compulsory for industrial workers and, in some countries, for all workers and employees. Coverage is now being offered to new groups of workers and to families.

Chile's National Health Service

In Chile, the National Health Service administers the majority of health agencies. This service is responsible for public health and medical care activities for 70 to 75 percent of the population, Bravo stated. Other organizations provide medical care to civil servants and white-collar employees, the military forces, the police force, prisoners, and railway employees, and an Accident Insurance Fund has its own medical services. Together, these organizations provide medical care to about 90 percent of the population of Chile, Bravo said, leaving only a very small group which finances its own medical care.

The three organizational principles of Chile's National Health Service have been centralization of directives and technical standards and decentralization of the operation of programs, integration of public health and medical care services, and participation of local communities in the planning and execution of

health programs, Bravo stated. This service is responsible for the provision of public health services to the whole population and provides medical care services for about 70 to 75 percent of the people. The National Health Service has established two priorities, he said. The first priority had been assigned to comprehensive medical care and protection of the health of mothers and children, the second to nutrition and food.

Although many people feel that the system could be improved, Bravo concluded, all agree that central administration of health services is worth while.

Unified Health Services In Malaya and Singapore

In underdeveloped countries with limited resources, better health can be achieved only by giving priority to the preventive services which are an investment for the future and using any remaining resources for providing curative services, stated Dr. I. S. Falk, of Stonington, Conn. Such a policy can only be carried out through a system of unified health services with salaried staff and regional services, he declared.

In Malaya and Singapore, competent administration of a unified health program has accomplished more with limited resources than would have been possible with separate preventive and curative programs, Falk said. In these countries, only nominal charges are made for personal services. Government health programs are supplemented by the services of private physicians for those who can afford them.

Health Services

The national health program in Malaya is the responsibility of the director of medical service, who works under the Minister of Health and Social Welfare, Falk stated. Local health functions are under the jurisdiction of the state or settlement health departments and local health departments, with partial

Federal control of funds and staffing. Health services provided by the government are supplemented on agricultural estates and mines by hospitals and clinics provided by employers; by voluntary health agencies; and, in urban areas, by private practitioners and hospitals, he said. Mobile health units operate on fixed schedules on the main roads and, in five states, on the rivers.

In Singapore, the responsibility for health services is divided, but coordinated, between the Ministry of Health of the colony and the health department of the city council. Water and sanitation are under the public works department. The official health agencies operate hospitals, clinics, dispensaries, and health centers.

Personnel and Funds

In Malaya, nearly all government health services have full-time staffs, although some part-time personnel are employed now when foreign recruitment is at a standstill. Falk said that in Singapore, with the increasing numbers of graduates from the university's medical school and the government's training school for nurses, there is no acute shortage of personnel.

Public funds finance both community and personal health services in Malaya, although fractional charges cover about 10 percent of the costs of personal services, Falk stated. The government devotes about 10 percent of its budget to health services, and about one-third of this amount is spent for preventive services, he said. With approximately an equal amount spent privately, aggregate expenditures for health are about 3 percent of the national income. In Singapore, aggregate public and private expenditures are about 4 percent of national income, government expenditures accounting for about one-half.

Vital Statistics

Birth rates are stable at 45 births per 1,000 in Malaya and 50 per 1,000 in Singapore, Falk reported. Death

dividuals and families did not receive many home visits or make many office visits in a given year, the cost to those who did require many services was high; 1 family required the equivalent of \$1.270 worth of such medical care in 1 year. The need for comprehensive medical insurance is further indicated by the fact that WMS subscribers seek medical care more often and, once care is sought, receive a greater number of services than do nonsubscribers to the plan.

The study, however, found no indication that WMS subscribers used an unreasonable amount of service. It has sometimes been assumed that subscribers to comprehensive medical care plans will seek the services of a physician for trivial reasons more often than will those with limited or no insurance. In Windsor, 33 percent of the subscribers to WMS requested no care at all during the year; 26 percent used the services of a physician only once, compared with 33 and 36 percent, respectively, of those in the limited and no-insurance categories. For all, with comprehensive, limited, or no insurance, the percentages using the service of a physician 2 or 3 times were about the same.

The additional cost of insurance providing comprehensive medical care has been willingly accepted by the population of Windsor. In fact, to retain their present benefits, 80 percent of WMS subscribers would pay increased premiums. Subscribers to limited benefit plans are willing to pay larger premiums for the WMS type of protection and, given the opportunity to enroll in an insurance plan, about two-thirds of the group who have no medical care insurance would be willing to pay the WMS premium.

Physician-Patient Relation

The fear that, with no direct payment required, patients will "shop around" for medical care has proved to be unfounded. About 92 percent of WMS subscribers have one physician to whom they go when they need medical care. Approxi-

mately the same proportion, about 70 percent, of WMS subscribers and nonsubscribers, received all of their home and office care from their regular physician, about 20 percent saw 2 different physicians, and very few in either group saw 3 or more practitioners.

Physician's Income

The effect of a fixed schedule of fees on the physician's income is a major issue in medical care insurance plans. Under WMS, Windsor physicians consider that their incomes equal or exceed the income they expected to be receiving at the current point in their careers. Fee schedules for WMS and private charges were quite similar. WMS subscribers provide 68 percent of the patient load of Windsor physicians and 60 percent of their total income. The majority of physicians considered the WMS fee schedule reasonable. About 70 percent of physicians reported that the plan had helped them gain a steady, assured income, and more than half said that the plan had helped them to build up their practices.

Administration and Costs

Apparently there is little friction or antagonism between WMS physicians and administrators of the plan. Administrative routines were generally satisfactory, and 96 percent of the physicians wanted no changes made in reporting methods.

Cost accounting has disproved the assumption that processing of small claims incurred under prepayment plans such as WMS approaches the cost of the claim itself. The average processing cost per claim was 14 cents, or 2.3 percent of the claim. The per service cost was 9 cents.

Latin-American Countries Extend Health Services

Economic, social, and educational factors have governed the organization of medical care in Latin America, stated Dr. Alfredo Leonardo Bravo, chief, social and occupational health section, World Health Or-

ganization, Geneva, Switzerland. No generalization should be made, he said, since local conditions in other countries may lead to an entirely different approach.

Relatively high salaries are found only in large cities, where industry is concentrated, Bravo said. A large proportion of the population lives in agricultural areas, where salaries are one-third to one-fourth of those in industrial areas. In 50 percent of the countries the average per capita income is only \$150 a year.

In the cities, a large proportion of industrial workers live in slums, Bravo said. Transportation and communications are poor and illiteracy is common. In 9 out of 20 Latin-American countries, 50 percent of the population is illiterate, and in one country the percentage is 89.5. Because of this pattern of poverty and ignorance, only a small minority are able to make any provision for medical emergencies. The large majority cannot, or are reluctant to, join a prepayment plan or even to pay for medical services.

Health Services

According to Bravo, the first health services in Latin America were provided through the *beneficencia* public hospitals, which were established in the 16th century. Hospitals still preserve the character of these early institutions in the provision of free care to the indigent by part-time physicians who receive only a token salary, he said.

In Latin America today, a basic need in any public health program is the medical treatment of patients, Bravo stated. However, during the treatment period, when the patient and his family are concerned with health questions, the physician has an opportunity to interest them in public health matters such as nutrition and sanitation.

The shortage and uneven distribution of health personnel have limited medical services in Latin America, prevented the development of a good system of death certification, and hampered the development of health statistics, Bravo declared.

"The specialist in communications, oral, written, and visual, is an important member of the modern health team. This fact is evident in the growing number of these personnel who are taking their places on the staffs of voluntary and professional health organizations and of official agencies at all levels of government."

The Health Message

JOHN D. PORTERFIELD, M.D.

A HALL OF HEALTH offers an excellent device for imparting knowledge about health and disease. We in the Public Health Service are proud to have had a part in the re-birth of a Hall of Health in the great Smithsonian Institution. The information on human anatomy and physiology which it presents should have a substantial impact on the knowl-

Dr. Porterfield is Deputy Surgeon General of the Public Health Service. The address was delivered at the ceremony opening the Hall of Health, Smithsonian Institution, Washington, D. C., November 2, 1957.

edge and behavior of the many thousands of visitors to the Institution each year.

Within the limits of time and space, the exhibit is probably among the best devices man has invented to communicate facts and ideas about the physical world. At its best, it combines the advantages of language and visual presentation in a specific and coordinated message with a high teaching potential. From the scratched stone drawings of ancient times to the sophisticated three-dimensional clay models of today, exhibits have been used to teach and to stimulate interest.

Certainly, the exhibit has long been an im-

rates have fallen to about 12 per 1,000 in Malaya, less than 9 per 1,000 in Singapore. In Malaya, infant mortality, formerly 100 to 200 per 1,000 births, is down to about 75. Maternal mortality in Singapore has dropped from 3 to fewer than 1 per 1,000 live births.

There are still many health needs in both countries, Falk stated. In

Malaya, tuberculosis is highly prevalent and as yet is not effectively controlled. Venereal disease is widespread, but the number of known cases is declining steadily. Rural health services are still in the developmental stage. Mental disease services are acutely inadequate. Health education still has difficult problems. In Singapore, the most

serious disease is tuberculosis, he said, although much has been done to combat it through direct attacks and health education.

The success of unified health services in Malaya and Singapore invites study of this pattern of services by health authorities for application to other underdeveloped countries, Falk concluded.

Universities Expand Curriculums

University of California. Three new courses in air pollution research and control enable graduate students to obtain advanced degrees with emphasis in that field in the School of Public Health or in the College of Engineering at the University of California, Berkeley.

These courses are urban meteorology; a lecture and seminar course in atmospheric pollution control; and a laboratory and lecture course in atmospheric pollution, including areawide monitoring. At least two of the subjects will be offered in a 6-week summer session in 1958.

A range of courses in allied fields may be used to complete requirements for an advanced degree. Further information may be obtained from Dean C. E. Smith, Public Health, Dean M. P. O'Brien, Engineering, or Professor B. D. Tebbens, University of California, Berkeley 4, Calif.

University of Michigan. During March 19-21, 1958, the University of Michigan School of Public Health, in collaboration with the Illuminating Engineering Society, will present a course on light and vision. The course is designed to identify and illustrate principles that underlie seeing in various lighting environments, and to outline measures by which these principles may be employed to obtain optimum conditions for seeing, particularly in schools and offices.

Further information may be obtained from H. E. Miller, Director, Continued Education Service, School of Public Health, University of Michigan, Ann Arbor.

From June 19 through August 1, 1958, the university will offer courses in public health statistics. These summer courses, elementary, intermediate, and advanced, are part of a cooperative program carried out by accredited schools of public health and supported by a research training grant from the National Institutes of Health, Public Health Service.

The summer program is designed for statisticians and epidemiologists with health agencies, health workers in voluntary agencies and pharmaceutical companies, and graduate students, research workers, and teachers in statistics and the health sciences.

For graduate students, these are credit courses. Deadlines for applications and transcripts are May 1 for nonresidents of Michigan and June 1 for residents. Application forms and further information can be obtained from the Director of the Summer Program in Public Health Statistics, School of Public Health, University of Michigan.

University of North Carolina. The department of sanitary engineering of the School of Public Health, University of North Carolina, now offers a graduate program leading to the degree of doctor of philosophy.

Candidates for the doctorate must have a master's degree in sanitary engineering, sanitary science, or sanitary chemistry and biology.

Fellowships and assistantships in research and teaching are available. Information may be obtained from the Department of Sanitary Engineering, P. O. Box 899, Chapel Hill, N. C.

portant means of communication in the fields of science and medicine.

The first American scientific exhibit as it is known today was displayed at the annual meeting of the Indiana State Medical Association in 1899. It consisted of a large collection of pathological specimens prepared by two Indianapolis physicians. It was such a great success that the two physicians displayed it the same year at the meeting of the American Medical Association held in Columbus, Ohio. Since 1900, the scientific exhibit has been an official part of the annual meeting of that association.

Today every sizable group in the health field gives the exhibit equal status with scientific papers and other original presentations.

But exhibits also have broader and more general uses. With the complex growth of our society, it has become necessary to use the exhibit not only as a professional and scientific tool but also as a means of reaching the general public. In 1904 the first tuberculosis exhibit for the general public was developed in Baltimore. It attracted nationwide attention, and was soon followed by a similar display at the American Museum of Natural History in New York where it was seen by thousands of visitors. The following year, the exhibit toured the Eastern States, under the sponsorship of the newly organized tuberculosis association and the guidance of one of the early disciples of visual health presentation, Evart G. Routzahn.

Since that time, the health exhibit has become a staple of numerous meetings and shows, and particularly of State and county fairs in rural areas. The modern era, however, ushered in many new and wondrous communications media: films, filmstrips, radio, and television. In comparison with these devices, the exhibit was thought to be archaic as a health education technique. Enthusiasm for exhibits seemed to wane.

Yet in 1939-40 the special hall of "Medicine and Public Health" of the New York World's Fair drew an estimated audience of 7½ million people. A popular health fair organized in 1954 in Miami, Fla., by the American Medical Association, with exhibits of the major professional, voluntary, and governmental health agencies of this Nation, attracted about 50,000

visitors in 4 days. There were comparable crowds at subsequent health fairs in such cities as Los Angeles, Cincinnati, and Oklahoma City.

I believe this is indicative of a number of things, but primarily of the tremendous popular interest in health matters. A recent survey, for example, revealed that newspaper readers wanted to see more articles on health than on any other single subject. Most of the major mass circulation magazines have special science and health departments. Popular pamphlets on health and hygiene reach millions of readers each year.

This reservoir of interest and awareness represents a challenge to us in public health as it does to those in the broad field of education.

As specialization in medicine and science becomes narrower and deeper, as new knowledge emerges from laboratories and research institutions, and as modern life becomes increasingly complex, it is essential that we rely more and more on easily understood methods of communication.

Since World War II, the volume of medical research in this country has increased about fivefold. We are beginning to make inroads on the problems posed by chronic illness and an aging population. There are things that can be done to treat some forms of heart disease, tests of value in diagnosing some forms of cancer, and new techniques in the treatment of mental illness. Thus, the pool of information which demands interpretation and application continues to grow.

To us in public health, this means that the specialist in communications, oral, written, and visual, is an important member of the modern health team. This fact is evident in the growing number of these personnel who are taking their places on the staffs of voluntary and professional health organizations and of official agencies at all levels of government.

For many years, for example, the Federal Government has made use of exhibits to help convey useful information of all kinds, both to professional groups and to the general public. In the health field, the medical museum was started by the Army during the Civil War. For almost a century, this nearby neighbor of the Smithsonian has made significant contri-

Hall of Health

Modern exhibit techniques in the Smithsonian Institution's new Hall of Health both educate and fascinate as they develop the theme: "Through the Ages, Man's Knowledge of His Body." Opened in November 1957 in the Arts and Industries Building, the hall stresses health rather than disease.

Exhibits illustrate effectively how the normal, healthy body is put together and how it works. Stages in embryo growth, birth and growth of a baby, bones and muscles, teeth, heart and circulation, digestion, respiration, endocrine glands, eye, ear, and nervous system are all represented.

Historical units display detailed reproductions of votive offerings, ancient manuscripts, and pages from the earliest printed books showing embryology, the skeleton, heart, brain, and digestive system as our ancestors knew them.

A center of attraction is the transparent figure of a woman (left) which, through electronics, light, and sound, shows the site and explains the function of major organs in the body. Other pushbutton exhibits reveal the inside of the human heart, anatomy of the tooth, site and action of endocrine glands, and brain function of a baseball player at bat.

The popular wall exhibit, "Growing, Growing, Grown," has a series of cutout forms of varying sizes (above) for determining typical heights of children at years 3, 6, 9, 12, and 15. Activities characterizing each age are illustrated in photographs mounted at appropriate intervals along the cutout series.

Audiometric Testing of School Children

SAMUEL M. WISHIK, M.D., ELIZABETH R. KRAMM, M.A., M.P.H.,
and ELVIRA M. KOCH, R.N.

HEARING of school children in Reading, Pa., was tested biennially during the 8 school years 1946-47 through 1953-54 by the staff of the Reading School District. In 1952, results of these tests were used in a study of 1,726 children in the fifth and sixth grades conducted under the auspices of the School Health Committee of the Pennsylvania Public Health Association. These children were selected because they had been tested biennially for a 6-year period. The 6-year study included prognostic implications and the relationship of hearing to academic retardation. In a report of the 1952 findings, the effectiveness of a biennial audiometric testing routine was evaluated, procedures for sweep check and threshold audiometric tests were described, and some of the definitions used in the study were given (1).

The present report covers the 8-year period 1946-54. The study continues to explore the question of the optimum periodicity of routine audiometric testing, measures the apparent impact of hearing impairment on academic progress, identifies certain prognostic signs, makes observations on the audiometric patterns of children between 5 and 14 years of age. Audiograms have been analyzed and the data are presented according to the ear involved and the age of the children rather than their

grade level. Since reasonably complete information on medical findings and treatment was not available, this important aspect of the problem cannot be reported. Administrative recommendations and research suggestions are offered in the light of the findings.

During the period from 1952 to 1954, 1,592, or 92 percent, of the 1,726 children previously reported on (1) had at least one audiometric test. Other than those who transferred out of the Reading public schools, only 36 children from the original study group who were still attending school were not tested.

Method

Frequencies on the audiogram were divided into low, middle, and high ranges. Frequencies 128 and 256 were included in the low range; 512, 1,024, and 2,048 in the middle range; and 4,096 and 8,192 in the high range. Frequencies 2,896 and 5,792, not done routinely, were included in the high range. Frequency 11,584 was not used in this study although it was included in the test procedure. Overlapping of frequency ranges was avoided in order to facilitate the drawing of statistical conclusions. In the remainder of the paper, frequencies will be referred to in round numbers.

To pass the threshold test, a child was expected to hear frequencies 250-4,000 at 20 decibels, frequencies 125 at 25 decibels, and frequencies above 4,000 at an average of 30 decibels. He was considered to have failed the test if his hearing fell below the standard in two or more frequencies in either ear. The average of frequencies above 4,000 was counted as one frequency.

Dr. Wishik is professor of maternal and child health and Miss Kramm is research associate in maternal and child health, Graduate School of Public Health, University of Pittsburgh. Miss Koch is a school nurse with the Reading School District, Reading, Pa. This paper was presented in part at the annual meeting of the American Public Health Association in Atlantic City, N. J., November 14, 1956.

butions to medical knowledge through its exhibits. The Public Health Service, too, has found this technique of communication invaluable, as have State and local health departments.

Today's challenge is no less great for such great institutions as the Smithsonian. The exhibit will always have a place in health education. As long as a youngster's curiosity is whetted by a visual presentation of the marvelous mechanism that is the human heart, then exhibits have no peer as a health teaching resource. As long as there is zest for knowledge, then there is a need for new and better and more vivid ways of bringing that knowledge to people.

Certainly we need to know more about how people learn through visual experience. We need to know how to improve the presentation of facts and information and arguments through visual means. We need to know how to take advantage of the "teachable moment" that a superior kind of exhibit can make possible.

Bruno Gebhard, director of the famous Cleveland Health Museum, has called a permanent health museum a "people's university," where visitors may see, study, and learn at their own pace and in their own way. In this new Hall of Health, the Smithsonian Institution has a "people's university" offering guidance to better health for more Americans.

Divorce and Annulment Data Collection Improved

An improved system of collecting statistics on divorce and annulment of marriage was adopted January 1, 1958, by the Public Health Service. A divorce and annulment registration area has been set up as a start toward obtaining figures on divorces and annulments as reliable and comprehensive as on births and deaths.

Since some States do not collect statewide figures on divorces and annulments, national statistics are based partly on estimates.

The new system not only provides a more accurate count, but also includes additional social and economic data on family breakdowns, information of value to courts, health and welfare agencies, and other groups dealing with dependency, juvenile delinquency, mental illness, and related problems.

The uniform data will be collected by the National Office of Vital Statistics, in cooperation with 14 States and 3 Territories: Alabama, Georgia, Idaho, Iowa, Montana, Nebraska, Oregon, Pennsylvania, South Dakota, Tennessee, Utah, Virginia, Wisconsin, Wyoming, Alaska, Hawaii, and the Virgin Islands.

failed." The failures were fairly evenly distributed within each age group (table 2). The high percentage of failures among children 14 years old and older should be disregarded since these are an atypical group. Sixty-five, or 7.5 percent, of 869 boys failed an audiometric test at some time during the study compared with 51, or 6.0 percent, of 857 girls.

The age distribution shown in table 2 is of no help in assessing the case-finding effectiveness of the biennial test program in children of different ages since it does not indicate how many new cases of hearing impairment were discovered in each age group. Nor would data on age at first discovery of hearing impairment give information on the increment resulting from a biennial test program unless all new cases had been tested in the biennium immediately prior to their first failure and had passed that test. Only these children can correctly be defined as "candidates for first failure by biennial retest."

Table 2. Number children tested and number and percentage who failed a test, according to age group at time of test

Age group (years)	Number tested	Failed	
		Number	Percent
5-7-----	1, 336	31	2.3
8-9-----	1, 595	64	4.0
10-11-----	1, 661	52	3.1
12-13-----	1, 467	45	3.1
14 and over-----	176	18	10.2

The percentage of such candidates who failed the test drops progressively with age, from 2.3 percent in the age group 8-9 years to 1.0 percent in the group 10-11 years old, to 0.8 percent in the next higher age group (table 3). In other words, the returns from routine biennial retesting become progressively smaller as the test program continues through the age groups.

In sharp contrast, the percentage of children who failed the first audiometric test increased with age (table 4). Obviously, delayed first testing occurred in a selected group of children who had a high rate of failure in the audiometric test. This kind of experience has contributed to the impression that newly developed

Table 3. Number of candidates for first failure at biennial retest, according to age group, and number and percentage of new cases found

Age group (years)	Candidates for first failure, at biennial retest ¹	New cases	
		Number	Percent
8-9-----	1, 243	28	2.3
10-11-----	1, 449	14	1.0
12-13-----	1, 329	10	.8

¹ "Candidates" are defined as children who had never previously failed an audiometric test and who had been tested in the immediately preceding age group.

hearing impairment occurs rather often among older children, whereas hearing loss probably existed for an unknown time prior to the time of the first audiometric test and prior to discovery of hearing impairment in many instances.

Data on longitudinal observations of the entire study group indicate that the results of the first tests given to a group of children make it possible to identify the majority of those who will fail an audiometric retest (table 5). Among the 1,305 children who passed the hearing test in the first age group, 43 (3.3 percent) failed a subsequent test, and only 12 (1.1 percent) of the 1,062 children tested in the group aged 12-13 years showed a failure at that time. On the other hand, among the 31 children in the first age group who failed the test, 15 (48.4 percent) failed again later, and 9 (29.0 percent) failed at 12-13 years of age.

Even though subsequent test histories of those passing and those failing the first audiometric test differ greatly, a subsequent failure

Table 4. Number of children taking audiometric test for first time and number and percentage of new cases discovered, according to age group

Age group (years)	Children taking test for first time	New cases	
		Number	Percent
5-7-----	1, 336	31	2.3
8-9-----	321	23	7.2
10-11-----	66	6	9.1
12-13-----	3		

The scale of severity of hearing impairment was: average hearing at 20 decibels or less, normal; 21-30 decibels, slight hearing loss; 31-40 decibels, moderate loss, and over 40 decibels, severe loss. Despite differences in passing standards, the same scale was applied to all three frequency ranges, in order to give full consideration to the possible significance of the very low and the very high ranges.

Periodicity of Testing

A routine biennial testing program should reach 50 percent of the total school enrollment each year. This was accomplished by routinely testing all children in the first, third, and fifth grades. More than 50 percent of the children were tested each year except in 1946-47 and 1947-48, the first 2 years of the study, when 48.1 and 46.7 percent, respectively, were tested. In addition to the routine tests in the odd grades, children were tested whenever special indications existed. Therefore, more than 50 percent were usually tested in any year. The largest number tested in any one year during the study period was 69 percent.

A tally of the number of children given an audiometric test in a particular year does not give a complete picture of the extent to which a given child is tested during his school career.

When a testing routine is administratively organized by school grades, the goal of biennial testing of a given child can be disrupted by late admission to school, early dropout from school, or repetition of grades. The age groups studied were 5-7, 8-9, 10-11, 12-13, and 14 years and over (table 1). Sixty-nine percent of the children were tested over the desired span of four or more 2-year intervals. Among the 116 children who failed a test at any time during the study, 70, or 60 percent, had this span of test coverage, and all but 3 of the remaining children were carried through 3 age groups.

The span of coverage by age groups indicates the time from beginning to end of the testing of any given child but does not imply that there was continuity or completeness of testing within that period. Table 1 indicates the longitudinal extent of the study and demonstrates that, despite the greater administrative problem, any routine program of periodic audiometric testing should be scheduled for individual children by age group rather than by academic grade.

Effectiveness of Periodic Retesting

Of the 1,726 children in the study, 116, or 6.7 percent, failed an audiometric test one or more times. These children are designated as "ever

Table 1. Age span of audiometric test coverage of total study population and of children who ever failed a test

tinuous hearing defect" after failure of an audiometric test had first occurred.

In view of the common occurrence of a short duration of hearing loss, is the biennial test interval too long? How many new cases would be discovered by an annual testing program? On 427 occasions, 302 children who had never failed a hearing test were retested 1 year after a previous test. In a sense, these children were "candidates for first failure by annual retest." Fourteen, or 3.2 percent, failed. The failure rate was 4.7 percent for the children under 10 years of age and 2.2 percent for those 10 years old or older.

Valid conclusions on the effectiveness of annual retesting of hearing cannot be drawn from a biennial testing program. In this study, some children were tested after a 1-year interval because of suspected hearing loss or repetition of a grade. However, appreciable numbers of children, particularly in the younger age groups, show hearing impairment some of the time within a 2-year interval. The only way to determine the value of annual retesting is to study the number of new cases found in an annual testing program.

Hearing Impairment on Entering School

An appreciable amount of hearing loss undoubtedly starts in the preschool years. Therefore, in the age group 5-7 years, children who

had hearing impairment at the time of the first audiometric test were compared with children who had normal hearing in the early school years but subsequently failed a hearing test. Criteria selected for comparison were continuity and severity of hearing impairment and involvement of one or both ears.

The 31 young children who had hearing difficulty when they entered school had the lowest proportion of "temporary-short" impairment of hearing, that is, no audiometric test failures after the first failure. Their percentage of temporary-short involvement was 36 compared with 63, 42, and 50, respectively, among the children who had normal hearing on admission but first failed a test in the later age groups (28 children in the 8-9 group, 15 in the 10-11 group, and 11 in the 12-13 group). The moderate difference between the entering pupils and older pupils is more noteworthy because it is directly contrary to the relatively common occurrence of temporary loss of hearing in the younger children as a whole. Four-fifths of the temporary-short failures in the study group occurred before 10 years of age. This tends to support the belief that the hearing impairment in entering pupils was not an acute transient episode but had been present prior to admission to school.

The same young children showed other evidence of having greater hearing damage than the older groups. At the time of first failure of

Table 6. Number and percentage distribution of children and separate ears ever failing an audiometric test, according to chronicity of hearing defect

rate of 3.3 percent in the passing group is still too high to discontinue retesting. But the justification for discontinuing testing grows stronger with each retest. Children who have passed all tests while in the first two groups are unlikely ever to fail subsequently. Eleven of 1,215 children in this category failed the test at 10-11 years, a failure rate of 0.9 percent, and only 7 out of 1,003, or 0.7 percent, of those tested failed in the group aged 12-13 years. When children miss taking a test in 1 of the first 3 age groups but pass in the other 2 groups, a similarly favorable pattern is present; only 1 out of 327, or 0.3 percent, failed after passing both tests done in the first 3 groups.

If routine audiometric testing had been discontinued for children successively passing the audiometric test in two early age groups without a history of any test failures, only approximately half the routine tests reported would have been done. If such a restricted procedure had been followed and if reliance had rested entirely on the routine testing program, 16, or 13.7 percent, of the failing children would have been missed. The suggestion that the age span

of the routine part of the test program be restricted will be modified later in the light of other findings.

Chronicity of Hearing Loss

A more detailed analysis of the longitudinal pattern of test results among the 116 children who ever failed a hearing test gives additional clues to answer the question, What is the best timing and frequency of routine audiometric testing? Most of these children did not have continuous hearing loss. They failed the audiometric test 275 times, or 49.3 percent of the 558 tests they took. The extent of "chronicity" among them and in their 177 ears whose hearing was ever affected is shown in table 6. The distribution of chronicity of hearing loss among pupils and among ears was similar. About half the audiometric test failures, those in the "temporary short" and "indeterminate" groups, were not repeated. There were other nonpermanent types of hearing loss; only 29 percent of the failing pupils and 24 percent of the failing ears fell into the definition of "con-

² Excludes 4 children whose record of grade repetition was unavailable.

NOTE: $\chi^2=14.89$ $P<.001$.

children who entered school late. Because these children often deviated from the routine grade placement, they tended to miss the scheduled tests for their group and to have recognition of their hearing impairment still further postponed.

Repetition of Academic Grades

Children who ever had hearing impairment during their school lives were twice as likely to repeat a grade as were other children (table 8). The magnitude of the impact of hearing impairment on academic status can also be sought through the grade repetition ratio, or the total number of grades repeated per 100 children. This ratio was 46 among children who ever failed an audiometric test compared with 20 among those who never showed hearing impairment. Thus, a child with a hearing defect not uncommonly repeats more than one academic grade during his school career.

In the present study it was not possible to examine the time relationship between hearing loss and school work because the data gave time of recognition of hearing loss rather than time of onset and time of repetition of a grade rather than time of the beginning of poor academic work. Comparison of age of grade repeaters with nonrepeaters at first audiometric test failure and separate comparison of audiometric test failers with nonfailers at first repetition of a grade showed no meaningful differ-

ences. There was no significant pattern of time relationship between first audiometric failure and first repetition of a grade in the 39 children who had both. Furthermore, there was greater delay in the time of audiometric testing of children who repeated grades than in the testing of other children, again apparently due to their falling out of step with the grades of their fellow pupils and being missed by the routine biennial testing program.

Grade at End of Observation

A combination of factors determines a child's academic status at the end of his school career. Therefore, the grade-age relationship at the end of the observation period was set up as the third index of possible impact of hearing impairment upon school work. Among the 114 children who ever failed an audiometric test, 38.6 percent had not reached their normal academic grade level at the terminal point of the study, whereas only 24.4 percent of the 1,609 children who had not shown hearing impairment at any time in their school career were behind their expected grade at the end ($\chi^2=13.66$ $P<.001$). The audiometric failure rate was far greater among children 2 years behind their age group than among those 1 year behind, and 3 times as high as among children at

Table 9. Number and percentage distribution of children with unfavorable audiometric test history, according to age-grade relationship at last observation

an audiometric test, the children in the youngest age group had a much higher percentage of bilateral involvement (71 percent) than those in the other three age groups (38, 47, and 45 percent, respectively), as well as greater severity of hearing loss in the middle frequency range. Average weighted scores of severity of hearing impairment for the four age groups were 150, 136, 86, and 50, respectively. Weights of 100, 200, and 300 were given for slight, moderate, and severe involvement of the middle frequency range. Poorer audiometric scoring in the youngest group is all the more meaningful in the face of the greater average acuity of hearing that is believed to be normally present in the early years.

Bilaterality and severity of hearing impairment may be related to age differences alone. One demonstrable age correlation in the total study population was the finding that younger children who fail an audiometric test show loss of hearing over a wider spread of frequencies than do the older children, whose hearing impairment is more likely to be focused on a narrower range of frequencies. The decrease in involvement of ranges with increasing age took place in the lower and middle frequencies rather than in the high tones. Age differences did not apply when hearing loss exceeded 40 decibels.

The extent to which a child suffers from his

hearing impairment is greatly influenced by whether one or both ears are affected. Among the 116 children who ever failed an audiometric test, laterality of involvement was known for 111. Half of these had bilateral loss of hearing at the time of first failure of an audiometric test. Among the group 5-7 years old, 69 percent of all failures were bilateral compared with 45-47 percent in each of the three older age groups.

Impact Upon Academic Progress

The possible effect of hearing impairment on a child's school work was studied in three ways: by age on admission to school, by repetition of academic grades, and according to grade at the end of observation.

Age of Admission to School

Among the children admitted to school at the normal age level (below 7 years), 5.9 percent ever failed a hearing test during the study period compared with 11.5 percent of those whose admission to school had been delayed. This is a statistically significant difference ($\chi^2=11.8$ $P<.001$), which may connote that undiscovered hearing loss was associated with and may have contributed to delay in acceptance at school. Also, 16 of the 28 children whose admission to school was delayed and who failed an audiometric test at some time failed the first time they were tested.

Intermittent hearing loss may exist prior to as well as after admission to school. Among the children who entered school late but passed the first audiometric test, the failure rate in the group aged 8-9 years was 3½ times the rate among children who were admitted to school at 5-7 years of age and passed their first audiometric test.

Gross delay in admission to school probably results from causes other than hearing defect. Among 218 children who entered school 1 and 2 years late, 12.0 and 13.5 percent, respectively, ever failed an audiometric test whereas, among the 26 children admitted to school 3 or more years late, only one instance of hearing loss was then or subsequently discovered (table 7).

The delay in receiving the first audiometric test was appreciably greater than usual among

¹ See footnotes to table 6.

² Excludes 10 ears with "indeterminate impairment" and 19 ears for which audiogram of first audiometric test failed was unavailable.

was: high plus middle, high plus low, and middle plus low.

With one exception, hearing impairment in two ranges increased the tendency to continuous hearing failure, as follows:

High plus middle was more chronic than high alone.

High plus middle was more chronic than middle alone.

High plus low was less chronic than high alone (the exception).

High plus low was more chronic than low alone.

Middle plus low was more chronic than middle alone.

Middle plus low was more chronic than low alone.

When hearing impairment existed in all three frequency changes, however, continuous failure was least likely.

Since the middle frequencies are the ones essential to functional hearing of speech, it is important that the prognostic significance of early loss of hearing in any frequency range must be assessed in relation to the end point of hearing impairment for the middle frequency range. Detailed analysis helps to explain the rank order of the frequency ranges in respect to their seeming prognostic significance for continuity of hearing impairment (table 11). Although the numbers of ears tested are small,

the differences in chronicity of hearing impairment in the middle frequency range are striking.

Four possible patterns of combination of frequency ranges include the high range. The highest percentages of continuous hearing impairment occurred when hearing impairment at the time of first audiometric test failure had been found in 3 of these 4 combinations (table 11). At first glance, this would suggest that any loss of hearing in the high range at the time of first failure of an audiometric test has great significance for continuity of hearing impairment. From a practical viewpoint, however, this is not so. The correlation existed only with the definition used for failing a threshold test, not with ultimate functional hearing as judged chiefly by middle frequency range loss.

End-point middle frequency range loss of hearing evidently related back to early middle range loss and did not occur to more than a slight extent when no loss of hearing in the middle frequency range had existed at the time of first failure of an audiometric test (table 12). Observation of these children over a longer period of time is necessary to determine whether the slight impairment of hearing in the middle frequency range that sometimes occurred ever becomes more significant. When the first test failure consisted of loss of hearing

normal grade level. In the group with 3 or 4 years of total academic retardation, however, the proportion with hearing impairment dropped, suggesting that other factors, such as mental retardation, entered more fully into the picture (table 9).

Detailed analysis of the longitudinal history of the children revealed a number of characteristic pictures. One group had hearing loss from the beginning and consistently thereafter. Half of these had fallen 2 or more years behind their normal academic level at the end of the study. These children usually had severe bilateral hearing impairment.

Early in their school careers, the children who probably had had a hearing defect prior to admission to school were grossly retarded academically. They were delayed in being admitted to school, missed their audiometric tests for varying lengths of time after admission, and repeated one or more grades before their hearing impairment was recognized. Strangely enough, half of them had only unilateral hearing defect. The nature of the hearing loss and its tendency to eventual improvement suggested an infectious etiology rather than that organic brain damage was the common basis for a nerve type of hearing impairment associated with mental retardation. Unfortunately, information on clinical findings and intelligence testing was not consistently available. In a number of slow-learning children, superimposed mild or moderate hearing impairment seemed to constitute a considerable handicap.

Prognosis

In order to make a retrospective appraisal of the prognostic implications of early audiometric test findings, the following indexes of the course of hearing impairment and its end results were established: chronicity; severity of hearing loss at the last audiometric test in different frequency ranges, especially the middle frequencies; and impairment of hearing in one or both ears at the last test. These indexes were analyzed in relation to (a) hearing impairment in frequency ranges at first test failure, (b) hearing impairment in combinations of frequency ranges at first failure, (c) severity of hearing impairment in the three frequency

ranges at first failure, (d) greatest severity of involvement in the three frequency ranges during the period of observation, and (e) consistency of laterality of hearing impairment.

Frequency Ranges

Among the children followed for 3 or more years after failure of an audiometric test, there was general correlation in the group as a whole between the number and severity of hearing impairments in any one of the three frequency ranges at the time of first test failure and the persistence and degree of loss in that same range at the time of the last test. The correlation held more strongly for high tones than for middle tones and for middle tones than for low tones.

Combinations of Ranges

Table 10 gives the percentage distribution of frequency ranges and combinations of ranges at the time of first failure of the ears that ever failed an audiometric test. Table 11 shows that among the 148 ears for which data on chronicity of hearing impairment were available, 25 percent had continuous audiometric test failure. The direct correlation between height of early hearing impairment on the frequency range scale and tendency of hearing deficit in that same frequency range to persist also was evident when combinations of two frequency ranges were affected at the first failure of a test. The rank order of percentage of continuous failure after early dual range involvement

² Excludes 10 ears with "indeterminate impairment" and 19 ears for which audiogram of first audiometric test failed was unavailable.

was: high plus middle, high plus low, and middle plus low.

With one exception, hearing impairment in two ranges increased the tendency to continuous hearing failure, as follows:

High plus middle was more chronic than high alone.

High plus middle was more chronic than middle alone.

High plus low was less chronic than high alone (the exception).

High plus low was more chronic than low alone.

Middle plus low was more chronic than middle alone.

Middle plus low was more chronic than low alone.

When hearing impairment existed in all three frequency changes, however, continuous failure was least likely.

Since the middle frequencies are the ones essential to functional hearing of speech, it is important that the prognostic significance of early loss of hearing in any frequency range must be assessed in relation to the end point of hearing impairment for the middle frequency range. Detailed analysis helps to explain the rank order of the frequency ranges in respect to their seeming prognostic significance for continuity of hearing impairment (table 11). Although the numbers of ears tested are small,

the differences in chronicity of hearing impairment in the middle frequency range are striking.

Four possible patterns of combination of frequency ranges include the high range. The highest percentages of continuous hearing impairment occurred when hearing impairment at the time of first audiometric test failure had been found in 3 of these 4 combinations (table 11). At first glance, this would suggest that any loss of hearing in the high range at the time of first failure of an audiometric test has great significance for continuity of hearing impairment. From a practical viewpoint, however, this is not so. The correlation existed only with the definition used for failing a threshold test, not with ultimate functional hearing as judged chiefly by middle frequency range loss.

End-point middle frequency range loss of hearing evidently related back to early middle range loss and did not occur to more than a slight extent when no loss of hearing in the middle frequency range had existed at the time of first failure of an audiometric test (table 12). Observation of these children over a longer period of time is necessary to determine whether the slight impairment of hearing in the middle frequency range that sometimes occurred ever becomes more significant. When the first test failure consisted of loss of hearing

in the high frequency range only, the high proportion of continuing failure of the audiometric test was made up almost entirely of persistent failure in the high range exclusively. Only 3 of the 13 ears in this group whose continuous failure of audiometric tests spanned 3 or more years developed even a slight degree of hearing loss in the middle frequency range. As an added check, audiograms were studied of 20 ears in 15 children which had been labeled

"borderline" rather than test failures. These children had shown some loss of hearing at the 6,000 or 8,000 frequency at one time or another but the loss was not enough to drop the high frequency range average below the passing standard. The majority of these children were 8 years of age when hearing loss was first noted and 13 of them were boys. The amount of loss was usually less than 50 decibels, in which case it disappeared within 1 or, at most, 2 years.

Audiometric School Testing Program

ADMINISTRATIVE RECOMMENDATIONS

The administrative recommendations listed below are based upon the findings of the study as they seem to fit together with other experiences, observations, and reports in the field of audiology and in school health programs. The word "school" applies to all grades through high school, without regard to structural or organizational separation. It is not intended that elementary, junior high, and high schools should treat their entering students as entirely new to an audiometric testing program but that continuity in testing should be attained by effective coordination of programs and prompt transfer of health records with the students.

1. School systems and health departments should work jointly for the development of comprehensive routine hearing screening programs among children of preschool age.

2. Organization of the audiometric test programs in schools should be based on ages of children rather than on grade grouping.

3. Screening tests should be given routinely:

a) To all students entering school for the first time. (Highest priority for prompt testing should be given to this group.)

b) Annually to all children under 10 years of age, except those who have ever had hearing impairment.

c) Possibly to all children just prior to their leaving school, espe-

cially among those who terminate their schooling before graduation.

4. Screening tests should be limited to the middle frequency range (500, 1,000, 2,000 decibels).

5. A makeup test should be arranged as soon as possible when children miss taking their routine tests, especially if these children fall into one of the special referral categories listed immediately below.

6. On referral, screening tests should be given to school children of any age when:

a) The teacher, parent, or child himself, suspects hearing is not normal.

b) Infections or allergic involvement of ear, nose, or throat are frequent or excessive.

c) Absenteeism is marked. (Criteria in terms of frequency, length, number, and type of absences, and ages of children should be established by the school health service.)

d) Academic work is poor. (Criteria should be established by the school according to its pattern of instruction and grading.)

7. Special effort should be made to obtain a test of hearing whenever a child has not entered school at the usual starting age.

When hearing impairment could be a contributing factor, no child should be denied admission or delayed in admission to school for supposed mental retardation or other

reason without attempting a test of hearing.

8. When a child fails a first screening test, the audiometric test should be repeated the same day, possibly with partial threshold testing in the middle frequencies. If he fails a second time:

a) His classroom teachers should be informed immediately of the possibility of hearing impairment.

b) A questionnaire on his earlier and recent hearing history should be filled out by the parents and child.

c) He should be given a threshold test covering frequencies 250-8,000 approximately 3 weeks afterwards, or later if respiratory infection is present.

9. When a child fails a threshold test:

a) The school health service should arrange to have him examined by an otologist.

b) He should be referred to the family physician or to the family's usual resource for medical care, and the parents should be given an interpretation of the audiometric test results and the otologist's findings.

c) Attempt should be made to send reports to the physician who treats the child.

d) Prompt and persistent follow-up steps should be taken by the school and the school health service to assure adequate care. Frequent threshold retesting may help to motivate the family toward medical care as well as to measure the child's progress.

The six children who had 50 decibels or more of loss retained this loss with minor fluctuations throughout the period of observation but never developed any other impairment sufficient to fail an audiometric test.

In the small group of five cases with the pattern of loss of hearing in the low plus high frequency ranges at the first failure of an audiometric test, the one ear that did not ultimately pass the test showed only slight loss of hearing

in the middle range frequency (table 12). Among the infrequent cases of initial loss of hearing in the low range only, one ear showed slight hearing deficit after 3 or more years.

It seems safe to conclude that if a child has or is likely to develop appreciable difficulty in hearing speech, this can usually be detected by audiometric testing of the middle frequency range only. Therefore, in sweep check screening tests time should not be spent on the low and

10. Once a child has been found to have hearing impairment:

a) He should be removed from the screening program and thereafter be given appropriate supervision and his hearing threshold should be tested as frequently as indicated by his clinical and academic progress.

b) Mild hearing impairment in a child becomes more handicapping when it is associated with some degree of mental retardation. Such a child should have as complete audiologic and psychological appraisal as possible so that an appropriate program can be planned for him.

c) Decision on modification of any child's education because of hearing impairment should first be based on his immediate needs rather than on the prognosis and thereafter

on careful observation and frequent reappraisal of the child rather than on the mere nature of his audiometric score. This works in two directions. On the one hand, mild loss of hearing on the audiogram with a clinical picture that usually bears a good prognosis does not preclude prompt aggressive treatment, possibly the temporary use of a hearing aid, and adaptations in the child's educational program. On the other hand, when the prognosis seems poor, definitive acceptance of that prognosis should be postponed and long-term educational and vocational plans should not be made until longitudinal observation and treatment for at least 2 years have permitted a more valid estimate of the ultimate outcome.

4. In a routine screening program limited to as few as three frequencies, it may be desirable and feasible to do a threshold test rather than a sweep check test. The threshold test might detect changes in a child's hearing in successive years even within the usual passing level, and it would establish for each child his own individual norm rather than pegging all children at the same norm.

With the use of antibiotics, otologists have been reporting the common occurrence of nonpurulent collections of fluid in the middle ear chambers, producing an initial drop in hearing of as little as 10 decibels. Prompt recognition of this relatively minor degree of impairment might lead to early and aggressive therapy and to prevention of permanent damage.

5. In the opposite direction to moving from a sweep check to a threshold test, there may be effective shortcuts to case finding. Comparative studies should be made on the use of a single frequency, such as 1,000, or of some sound other than a pure tone but composed primarily of the middle frequencies. Verbal tests need further analysis. These have been discussed by Lee Meyerson in *Hearing for Speech in Children: A Verbal Audiometric Test* (Supplementum 128 to *Acta Oto-Laryngologica* 1956).

6. Evaluation should be done of the case-finding effectiveness of the several special referral criteria suggested in this paper.

7. Time and cost studies of the various audiometric screening methods are essential to help determine the most practicable procedures for testing large numbers of children.

SUGGESTIONS FOR RESEARCH

A variety of audiometric screening methods deserve comparative studies.

1. The increment of new cases found by an annual retest should be studied in a school screening program in which such annual testing is done routinely.

2. The effects on meaningful case finding of narrowing the span of screening to the middle frequencies and to the younger ages, as here recommended, should be studied in additional school programs.

3. If the pure tone sweep check method is used, studies should be done on the advisability of moving the screening decibel level closer to

the so-called zero line in the middle frequency range. The greater artifact of ambient noise in the low frequency range has heretofore been the major deterrent to establishing a more rigid passing standard for audiometric tests.

Change in the passing standard would also be in keeping with the greater acuity of hearing that is normally present in young children. Audiometers have been calibrated to fit the hearing of adults, not children. The case-finding and prognostic value of a more rigid passing standard in the middle frequency range should be checked by comparative studies.

high frequency ranges. When, however, one moves from finding new cases by screening tests to assessing, treating, and educating children with known hearing impairment, knowledge concerning any associated impairment of hearing in the low and high frequencies is important. A number of findings indicate that low and high frequency ranges should be included when threshold tests are done on children with known or suspected loss of hearing.

The severity of end-point middle frequency range loss of hearing depended on early impairment of hearing in the middle frequency range in combination with 1 or 2 other frequency ranges (table 12) in the same rank order as the tendency of such combinations of ranges to persist (table 11), as follows: middle plus high, middle plus low, and middle plus high plus low.

Severity of Hearing Impairment

The mere presence at the time of first audiometric test failure of loss of hearing in either the low or high frequency range combined with impairment of hearing in the middle frequency range was more significant than the severity of early impairment in the low or high range. Among the ears with loss of hearing in the middle range plus high range at the first failure of an audiometric test, the group with

the highest proportion of persistence of hearing impairment (63.6 percent, table 11), there was no relationship between the severity of loss of hearing in the high range at the first test failure and loss of hearing in the middle range at the last test. There was, however, striking correlation between the severity of hearing impairment in the middle frequency range at the first and last tests.

Among the 19 ears with loss of hearing in the middle plus low frequency ranges at first failure of an audiometric test, the extent of first impairment of hearing in either the middle or low range had no relationship to whether an ear later passed or failed the audiometric test or to the severity of end-point middle frequency range loss of hearing when the ear did fail the test. Four ears showed audiometric test failure after the first test. In none of the rare instances of initial loss of hearing in the middle frequency range only was there any hearing impairment after a span of 3 or more years.

Of particular interest is the large group of ears that showed "across the board" loss of hearing in all three frequency ranges at the first failure of an audiometric test. Only 11 percent of these ears followed for 3 or more years had more than slight middle range loss at the last test. Even among 10 children who had severe

loss of hearing in all 3 frequency ranges at the first failure of an audiometric test, 9 finally passed the sweep check test. Therefore, among children attending day school, "across the board" loss of hearing on audiometric test usually is the result of acute rather than chronic hearing impairment.

In this study, loss of hearing in some of these children may have been due to impacted wax, although case histories indicated the frequent existence of nasopharyngeal infection. This finding is in keeping with the experience of clinicians that there is a general "flattening" of hearing level associated with acute middle ear infection and that this flattening moves either toward recovery or toward persistent loss of hearing of a less even nature. The broad span of frequencies affected in the flattening gives a favorable rather than an unfavorable prognosis as long as the impairment is not excessive.

The prognostic importance of "across the board" loss of hearing was borne out by a look at another group of children. This group was composed of seven children who were in the same age group as the study population and whose families resided in the Reading School District but who attended the State residential school for the deaf. All of these children had consistent "across the board" impairment of hearing from first to last tests, with much greater decibel loss than the children in the study. No child in the study population, for example, ever had an audiogram with every frequency reading at 60 decibels or more. Although severity and duration of "across the board" hearing impairment are of some assistance, it is not always possible to distinguish between the child whose hearing will clear up partially or completely and the child who will remain seriously handicapped. What is vital is the fact that the prognosis for many children with considerable hearing loss covering a wide spectrum of frequencies need not be a pessimistic one.

An attempt was made to derive prognostic significance from the greatest degree of hearing impairment in each frequency range in any ear during the study period. Continuity of failure of audiometric tests or intermittency of hearing impairment ending in failure of the

test correlated directly with increasing severity of the poorest test result in the middle frequency range. The correlation was even greater with poor test results in the high frequency range. On the other hand, the ears that remained normal in the low frequency range despite failing one or more audiometric tests had the poorest prognosis for chronicity of hearing impairment. Evidently, unevenness in audiometric test score is more indicative of probable persistence of hearing impairment than is "across the board" homogeneous severity of hearing loss. This applies not only to irregular impairment of hearing in the three frequency ranges but to uneven severity of hearing loss from one frequency to another within any range.

Laterality of Impairment

Some interesting prognostic inferences may be drawn from the data on consistency of hearing impairment of one or both ears in the same children. Among the 58 children who failed the audiometric test in more than 1 year, 38 percent had unilateral involvement only, 24 percent had bilateral involvement only, and 38 percent fluctuated between unilateral and bilateral involvement. In almost no instance did unilateral failure move from one ear to the other, and very rarely did hearing loss progress from unilateral to bilateral involvement. The change, if any, was usually in the other direction. In general, a better prognosis for hearing status at the last audiometric test was suggested when there was fluctuation between bilateral and unilateral hearing loss during a child's school career than if the loss was always unilateral or always bilateral (table 13).

At the end of the observation period, 13 children, or 8 per 1,000, had bilateral hearing loss of more than 30 decibels in the middle frequency range. Seven were in the school for the deaf; six were from the Reading School District biennial audiometric test program. These six children were the ones with a definite deficit for hearing speech. Four had had hearing difficulty when they entered school; two developed hearing difficulty later. In the entire study population, there was only one child who had had the same degree and type

Table 13. Number of children who failed more than one audiometric test and number and percentage of failures at time of last test, according to laterality of impairment in all test failures

Laterality of ear involvement when failing tests	Children failing more than 1 test	Failed last test	
		Number	Percent
Total-----	58	36	62.1
Always unilateral-----	22	17	77.3
Always bilateral-----	14	10	71.4
Mixed laterality-----	22	9	40.9

of hearing loss for 2 or more years but whose hearing at the last observation was no longer impaired to the same extent as at the beginning of the study. Information was not available on homebound children with other handicaps that could affect their hearing.

Summary

During an 8-year study of 1,726 school children aged 5-14 years in Reading, Pa., 116, or 6.7 percent, ever failed an audiometric test.

The increment of new cases of hearing impairment found by a biennial retest routine was 2.3 percent among "candidates" 8-9 years old, 1.0 percent in the group aged 10-11 years, and 0.8 percent in those 12-13 years old.

Among children 5-7 years of age who passed their first audiometric tests, 3.3 percent failed a subsequent test. Among children in this age group who failed their first audiometric test, 48.4 percent failed later tests. When children passed all their tests before 10 years of age, less than 1 percent failed thereafter.

Hearing impairment persisted without interruption in 28 percent of the children and in 24 percent of the ears that ever failed an audiometric test.

Young children whose hearing impairment was discovered about the time they entered school had more severe types of hearing impairment than other children, suggesting that the condition had probably existed for some time prior to admission to school.

Rates of delayed admission to school, delay in receiving audiometric tests, repetition of

academic grades, and retarded grade status at the end of the observation period were higher for children who ever failed an audiometric test than for other children. Moderate unilateral impairment of hearing as well as severe or bilateral loss of hearing seemed to constitute an educational handicap, especially during the early years of learning language, reading, and spelling, when missing parts of the sounds might almost completely prevent a child from grasping the meaning of what he hears.

Ultimate loss of hearing in the middle frequency range after failure of an audiometric test did not often occur unless there had been initial impairment of hearing in the middle frequency range. With initial middle frequency range loss of hearing alone, the prognosis was good; initial middle range plus low frequency range loss signified a poorer prognosis, and initial middle plus high frequency range loss, the least favorable prognosis.

Initial "across the board" loss of hearing in all three frequency ranges at 40 decibels or less usually denoted a good prognosis. More severe and early "across the board" impairment of hearing occurred in cases of persistent deafness.

Unevenness of audiograms in severity of hearing impairment and in frequency ranges gave a poorer prognosis than evenness except for the most severely affected ears.

Hearing impairment in 38 percent of the children who failed the audiometric test in more than one year was unilateral whenever they failed the tests, almost always in the same ear; in 24 percent, always bilateral; and in 38 percent, impairment fluctuated between unilateral and bilateral involvement. Such fluctuation gave a better prognosis than when hearing loss was always unilateral or always bilateral.

Eight children per 1,000 studied had an end point of bilateral hearing impairment of more than 30 decibels in the middle frequency range.

Milk Sanitation Honor Roll for 1956-57

Sixty-four communities have been added to the Public Health Service milk sanitation "honor roll," and 45 communities on the previous list have been dropped. This revision covers the period from January 1, 1956, to December 31, 1957, and includes a total of 266 cities and 70 counties.

Communities on the "honor roll" have complied substantially with the various items of sanitation contained in the milk ordinance suggested by the U. S. Public Health Service. The State milk sanitation authorities concerned report this compliance to the Public Health Service. The rating of 90 percent or more, which is necessary for inclusion on the list, is computed from the weighted average of the percentages of compliance. Separate lists are compiled for communities in which all market milk sold is pasteurized, and for those in which both raw milk and pasteurized milk is sold.

The suggested milk ordinance, on which the milk sanitation ratings are based, is now in effect through

This compilation is from the Division of Sanitary Engineering Services of the Bureau of State Services, Public Health Service. The previous listing, with a summary of rules under which a community is included, was published in Public Health Reports, October 1957, pp. 943-946. The rating method was described in Public Health Reports 53: 1386 (1938). Reprint No. 1970.

voluntary adoption in 477 counties and 1,398 municipalities. The ordinance also serves as the basis for the regulations of 34 States and 2 Territories. In 14 States and 2 Territories it is in effect statewide.

The ratings do not represent a complete measure of safety, but they do indicate how closely a community's milk supply conforms with the standards for grade A milk as

stated in the suggested ordinance. High-grade pasteurized milk is safer than high-grade raw milk because of the added protection of pasteurization. The second list, therefore, shows the percentage of pasteurized milk sold in a community which also permits the sale of raw milk.

Although semiannual publication of the list is intended to encourage communities operating under the suggested ordinance to attain and maintain a high level of enforcement of its provisions, no comparison is intended with communities operating under other milk ordinances. Some communities might be deserving of inclusion, but they cannot be listed because no arrangements have been made for determination of their ratings by the State milk sanitation authority concerned. In other cases, the ratings which were submitted have lapsed because they were more than 2 years old. Still other communities, some of which may have high-grade milk supplies, have indicated no desire for rating or inclusion on this list.

Communities awarded milk sanitation ratings of 90 percent or more, 1956-57

t Availability of Older People

Older persons has been a considerable interest in recent years. The interest has centered on the attitudes of society toward employment and retirement. It is given to the extent to which older people themselves are physically able to enter the

labor force. The questions in the third and fourth sections were asked alternatively of persons who were or were not in the labor force. These sections included questions on present or previous occupation, attitudes toward employment and retirement of older persons, and, for unemployed persons, conditions

The study reported upon in this monograph is: the individual's subjective assessment of health and fitness for work. A scale for measuring his degree of interest in entry into the labor force, and the degree of job opportunity existed. It is shown how health, attitudes, family and other factors are related to entry or reentry into the labor

force. The study was considered to be equally as valid as the data derived from the study.

The study therefore emphasizes the methods used to overcome procedural difficulties encountered, and the results that were made, so that other communities interested in obtaining information on the availability for work among older persons might profit from this experience. The study was conducted in Hagerstown, Md., in a sample of 1,114 dwelling units, 615 of which had one or more persons 45 years of age or older. An interview was conducted with only one of these older persons at each household. The sampling plan devised for the survey is similar to the use of many communities for labor force or employment surveys as well as for other purposes. This sampling method has been described by Woolsey in Public Health Monograph No. 40.

The questionnaire contained four sections. The first was used to obtain basic household and personal data, the second, to obtain information

No. 51

The accompanying summary covers the principal findings presented in Public Health Monograph No. 51, published concurrently with this issue of Public Health Reports. The author is with the Division of Public Health Methods, Public Health Service.

Readers wishing the report in full may purchase copies of the monograph from the Superintendent of Documents, Government Printing Office, Washington 25, D. C. A limited number of free copies are available to official agencies and others directly concerned on specific request to the Public Inquiries Branch of the Public Health Service. Copies will be found also in the libraries of professional schools and of the major universities and in selected public libraries.

NOTE: In these communities the pasteurized market milk shows a 90 percent or more compliance with the grade A pasteurized milk requirements, and the raw market milk shows a 90 percent or more compli-

ance with the grade A raw milk requirements, of the milk ordinance suggested by the United States Public Health Service.

Note particularly the percentage of the milk pasteurized in the vari-

ous communities listed. This percentage is an important factor to consider in estimating the safety of a city's milk supply. All milk should be pasteurized, either commercially or at home, before it is consumed.

Radiation Detection Through Hair-Root Changes

The amount of radiation a person has received may be measured by examining the hairs from his scalp if his head has been exposed, according to Dr. E. J. Scott and Dr. R. P. Reinertson of the National Cancer Institute, Public Health Service, who reported their findings in the September issue of the *Journal of Investigative Dermatology*.

The paper, "Detection of Radiation Effects on Hair Roots of the Human Scalp," describes a study of the hair roots of cancer patients undergoing radiation therapy at the National Cancer Institute.

As early as 4 days following radiation, abnormal changes, such as progressive thinning of the hair roots, were observed.

Employment Availability of Older People

EMPLOYMENT of older persons has been a subject of considerable interest in recent years. Much of this interest has centered on employment practices and the attitudes of society with respect to employment and retirement. Less attention has been given to the extent to which unemployed older people themselves are willing and are also physically able to enter the labor force.

The purposes of the study reported upon in this monograph were:

- To measure the individual's subjective assessment of his health and fitness for work.
- To devise a scale for measuring his degree of availability for entry into the labor force, assuming a suitable job opportunity existed.
- To determine how health, attitudes, family composition, and other factors are related to availability for entry or reentry into the labor force.

Methodology was considered to be equally as important as the data derived from the study. The report therefore emphasizes the methods employed, procedural difficulties encountered, and errors that were made, so that other communities interested in obtaining information on health or availability for work among older people might profit from this experience.

The study was conducted in Hagerstown, Md., in a sample of 1,114 dwelling units, 615 of which included one or more persons 45 years of age or older. An interview was conducted with only one of these older persons at each household. The sampling plan devised for the survey is adaptable to the use of many communities for health or employment surveys as well as for other purposes. This sampling method has been described by Woolsey in Public Health Monograph No. 40.

The questionnaire contained four sections. The first was used to obtain basic household and individual data, the second, to obtain informa-

tion on the health and limitations of the older person selected for interview. The questions in the third and fourth sections were asked alternatively of persons who were or were not in the labor force. These sections included questions on present or previous occupation, attitudes toward employment and retirement of older persons, and, for unemployed persons, conditions

Lawrence, Philip S.: Availability for work: Chronic disease and limitation of activity. Public Health Monograph No. 51 (PHS Pub. No. 556). 44 pages. U. S. Government Printing Office, Washington, D. C., 1958. Price 35 cents.

under which they would be willing or able to accept employment. Although the questionnaire was pretested and modified, a number of problems in the design of the schedule and wording of the questions became evident when the final form was used in the field. These problems are discussed in detail in the monograph.

Availability for Work

Comparisons between people over age 45 years who are in the labor force and those who are not reveal differences with respect to health, physical limitations, education, marital status, and attitudes toward employment and retirement. The magnitude of the differences shows that employed persons of these ages are a select group and that assumptions concerning the labor force potential of unemployed older persons cannot be made from studies on employed persons nor from usually available population statistics, such as age and sex.

A scale of availability for employment was developed from answers to questions about job-seeking activities, interest in applying for employment, and physical disability. About one-quarter of the men and one-eighth of the women between ages 45 and 65 years considered themselves available for work. Only about 6 percent of men and women over age 65 indicated that they would consider employment. These proportions vary when considered in relation to the length of time since last employment and the kinds of previous occupations. In general, occupational groups which require the least skill or experience contain the highest proportions of persons who consider themselves available for reemployment. The scale used to rate availability shows logical relationships to household characteristics, attitudes toward employment and retirement, sex, and age. Furthermore, the answers regarding specific conditions under which individual respondents would be willing to accept employment were, in the main, consistent with other answers given in the interview. For example, among persons rated high in employment availability, the type of work that they would consider applying for was consistent with their previous experience and educational level.

Although availability for work is associated

with health, still about one-quarter of the people who said they would consider employment had reported both chronic conditions and limitations of activity. In assessing the potential for employment of older people it is not sufficient to obtain information only on willingness to work. Information is also needed on degrees of physical limitations that may constitute practical barriers to employment.

Illness and Limitation of Activity

The primary purpose of obtaining information on chronic illness and limitations was to relate it to employment availability. However, it was thought that there is enough current interest in health surveys to warrant a discussion of this subject in a separate section of the monograph. Since the collection of a large volume of morbidity data was not a primary objective of the study, the data from the sample of 600 households in Hagerstown cannot be generalized to other areas but may be useful as guides in health survey planning in other areas.

This survey differs from most household illness surveys in that each person on whom information was obtained responded for himself. This avoids any bias, particularly with respect to sex differences, that results from acceptance of proxy respondents. In this study, as in others, women have a higher prevalence rate of chronic conditions than do men of corresponding ages. The higher rate for women exists only from conditions reported to be of an episodic nature. More severe conditions affecting the respondent "all the time" existed in equal proportions of men and women.

Ninety percent of the men between the ages of 45 and 64 years who were not in the labor force reported one or more chronic conditions which affected them all the time. Only 14 percent of men 45 to 64 years old who were in the labor force reported such conditions. Similar differences, though not to such a marked degree, exist for women 45 to 64 years of age and for men and women aged 65 years and over. No association between labor force status and the prevalence of chronic conditions which affect the person only "off and on" are evident from this study.

A qualitative scale of activity limitations was

tried in the Hagerstown survey and no difficulties were encountered in its use. The scale ranged from reduction in various types of activity to confinement in a bed or chair.

The degrees of limitation were related to age, sex, employment status, availability for work,

and type and severity of conditions reported. Associations found indicate that a qualitative scale of limitations is a useful yardstick for measuring disability and may, for certain purposes, be more practical than quantitative measures such as days in bed.

Mexican Medical Curriculum

Teaching preventive medicine and public health at 10 medical schools in Mexico has been stimulated through a project of the Dirección de Estudios Experimentales en Salubridad Pública. Three more medical schools have established departments of preventive medicine and 7 others are collaborating with the Dirección. A University of Guadalajara professor, studying at the School of Public Health under a Dirección scholarship, will return to head his school's department of preventive medicine. Through several projects a total of 17 physicians and 4 nurses are studying on Dirección scholarships at the School of Public Health.

—TROI E. JOHNSON, M.D., M.P.H., *formerly chief, health, welfare, and housing field party, U. S. Operations Mission, Mexico.*

Disease Intelligence Center

The Philippines' Department of Health is planning a disease intelligence center to provide information for the prevention and control of disease. Communicable illnesses are still the country's major health problem and many are unidentified and unrecognized. Sudden outbreaks often reach epidemic proportions.

The center will centralize three preventive medicine disciplines—statistics, epidemiology, and laboratory—and supply data to plan and evaluate health

services involved in preventing and controlling communicable diseases. To provide maximum facilities and personnel, the center will coordinate the cooperating hospitals, medical schools, and other government agencies.

The center will employ a special mechanism for reporting unusual outbreaks of disease, using city, provincial and rural health personnel, private physicians, hospitals, school authorities, and other selected sources. The information the center collects will supplement the usual morbidity and mortality reports.

—FRANK S. MORRISON, *analytical statistician, U. S. Operations Mission, Philippines.*

Jiquilisco's Health Center

The people of Jiquilisco, El Salvador, wanted a health center so much that at a general meeting they donated close to 25 percent of the materials as well as the labor and transportation needed to build it. The sanitarian consultant has been working with the USOM community development specialist, organizing a program for this town of 6,000.

—VERNON R. SCOTT, *sanitarian consultant, Health and Sanitation Division, U. S. Operations Mission, El Salvador.*

First Rural Health Unit

The first rural health unit in Liberia was dedicated at Salala in the Central Province. The unit has a 5-bed ward, delivery room, clinic, combination drug room and laboratory, and waiting room. A midwife, nurse, and dresser staff it, and a doctor visits once a week. The rural health center is part of the effort to extend services to women and children.

How to Study the Nursing Service of an Outpatient Department

PHS Publication No. 497. 1957. By Apollonia O. Adams. 75 pages. 50 cents.

Intended primarily as a guide with which nursing personnel and nursing service administrators of an outpatient department can study how closely their services relate to the goals of their agency or institution and to the goals of good nursing service, this manual can be used to analyze functions and needed skills of all personnel under nursing supervision.

The manual is a collection of a series of studies, such as utilization of nursing personnel, patient waiting, facilities for teaching, record flow in relation to nursing service, and other factors which affect nursing personnel. These can be made individually or as one large study.

This is the fourth in a series developed by the Division of Nursing Resources, Public Health Service, for use by hospitals and others desiring to study nursing services.

The Clinical Center: Current Clinical Studies and Patient Referral Procedures

PHS Publication No. 284. Revised 1957. 32 pages.

Intended for physicians interested in the possibility of referring patients for study to the Clinical Center, National Institutes of Health, Public Health Service, this revised brochure outlines the referral procedures in detail.

The principal study projects for which patients are currently being admitted, and some of the more important diagnostic or other criteria for admission are described briefly.

This publication is revised period-

ically. Hospitals, clinics, medical schools, medical societies, medical journals, and individual physicians will be placed on a mailing list on request to the Director of the Clinical Center, National Institutes of Health, Public Health Service, Bethesda, Md.

The Cancer Quacks

PHS Publication No. 559. 1957. By Charles S. Cameron. 18 pages.

The dangers to life and health for those who fall victim to cancer quacks are set forth with force and clarity in this chapter from Dr. Cameron's book *The Truth About Cancer*, written for the layman.

He describes the three kinds of quack, the quacks themselves, and their patients, and tells what can be done about quackery.

The policy of the National Cancer Institute, Public Health Service, regarding investigation or evaluation of proposed cancer treatment is given in the appendix.

The Older Person in the Home

PHS Publication No. 542. 1957. 34 pages. 20 cents.

Families with older members living in their homes are given specific suggestions for health and happiness in the three-generation household. Some of the most common problems confronting them, physical, mental, and emotional, are discussed.

One section of the booklet is devoted to the more difficult problems that arise when the eldest member is seriously handicapped, and another section gives pointers to consider if it seems necessary for the aged person to move into a nursing home or old people's home.

Although addressed primarily to the housewife, as the key person in the household, the booklet will also

be of interest to public health workers, social workers, religious leaders, and others who provide services to elderly persons and their families.

A bibliography, including available films, is provided.

Municipal Water Facilities, Communities of 25,000 Population and Over

PHS Publication (unnumbered). 1957. 163 pages.

Water supply data for organized community water facilities of approximately 850 municipalities in the United States and Territorial possessions as of December 31, 1956, are inventoried. These data reflect changes during the previous year.

The inventory is designed to aid industry and government in planning broad water developments as well as in planning for industrial expansion and national emergencies.

Information Leaflet

THE FOOD YOU EAT AND HEART DISEASE. *PHS Publication No. 537.*

(Health Information Series No. 89) 1957. 11 pages. \$5.00 per 100. Answers many questions asked by the general public on relation of diet to cardiovascular disease. Gives five diet tips for people with any kind of heart disease.

This section carries announcements of new publications prepared by the Public Health Service and of selected publications prepared by other Federal agencies.

Unless otherwise indicated, publications for which prices are quoted are for sale by the Superintendent of Documents, U. S. Government Printing Office, Washington 25, D. C. Orders should be accompanied by cash, check, or money order and should fully identify the publication. Public Health Service publications which do not carry price quotations, as well as single sample copies of those for which prices are shown, can be obtained without charge from the Public Inquiries Branch, Office of Information, Public Health Service, Washington 25, D. C.

The Public Health Service does not supply publications other than its own.

Medical care expenditures of farm-operator families have increased sharply in the past 20 years, with a decrease in the farm-urban disparity, improvement in the relative position of southern families, and changes in the distribution of the medical care dollar.

Farm Medical Care Expenditures

JEAN L. PENNOCK, M.A.

FARM-OPERATOR families in 1955 spent, on the average, \$240 per family for medical care. Spending per person in these families amounted to \$63. Comparison of this figure with per person expenditures of \$10 by farm families and \$19 by urban families in 1935-36 (1), \$15 by farm families and \$32 by urban families in 1941 (2), and \$65 by urban families in 1950 (3) reveals a tremendous increase in the level of expenditures in the past two decades and indicates that farm and urban families are becoming more similar in spending for medical care.

Part of this increase in medical care expenditures is due to the change in price level (4). But when this is taken into account, a tripling in medical expenditures for members of farm families since 1935-36 and a doubling since 1941 remain (table 1).

Beyond the rise in prices, it is difficult to pinpoint factors that explain the change in medical care expenditures. It is easier to point out some of the things that are not responsible.

Only part of the change can be attributed to an increase in the income of the farm population; although the real income of farmers rose rapidly during the early years of the war and remained relatively constant at a high level from 1943 through 1946, it then began a slow decline

that, with interruptions, continued through 1955 and brought it in that year to a point only about 20 percent above the 1941 figures (5). Only fragmentary data are available on the movement of farm-family expenditures for medical care between 1941 and 1955, but indications are that in dollars of constant purchasing power they have risen more or less continuously throughout the period. An estimate for the farm population in 1945, derived from a survey in the North Central region and in the South, would indicate that at that time medical care expenditures were far short of the 1955 level. Home accounts of a group of farm families submitting their records to State universities show that the medical care expenditures of this group rose steadily throughout the period (6). These account-keeping families are not typical of all farm families, but it is assumed that their accounts reflect the trend in farm spending.

Our aging population might be expected to push medical costs upward, but on examination the effect of the change in the age distribution of the farm population is found to be negligible. Increases in the proportion of children, the age group with the lowest average expenditures, appear to cancel out increases at the other end of the age range, where expenditures tend to be high. This conclusion assumes the relationships in expenditures by age found by Mushkin in the 1950 urban data (7).

The explanation for the increase in farm expenditures for medical care must be sought

Miss Pennock, a home economist, is with the Institute of Home Economics, Agricultural Research Service, U. S. Department of Agriculture.

in part in the wide complex of factors determining the general living expenses among farm families, for the medical care situation is not an isolated phenomenon. Expenditures for all categories of consumption combined have risen almost as much proportionally as have medical care expenditures, and a few categories have shown even sharper increases. In spite of the very large increase in medical care expenditures, this category accounted for only 1 percent more of the total consumption expenditures in 1955 than it did in 1941.

Gains Since 1941

For the same array of goods and services included under medical care in the 1941 study, farm families were spending \$235, on the aver-

Table 1. Main categories of medical care expenditures in current dollars and in dollars of constant purchasing power, farm-operator families and single farm operators

Expenditure category	1955		1941	1955 as a percent of 1941 computed in 1941 dollars

Medicines and drugs ²	39	29	10	290
Other ³	13	7	5	140

¹ Adjusted by the consumer price index (4). The most suitable component of the index has been applied to the individual categories of medical care expense and the total obtained by addition. Since health insurance was not included in the index in 1941, hospital care, the major component of health insurance, was used for that year.

² In this table, vitamin and mineral preparations, a component of medicines and drugs in the 1955 data in tables 2, 3, and 4, have been excluded to achieve comparability with the 1941 data.

³ To achieve comparability with the 1941 data, unitemized expenditures reported on the 1955 schedules have been allocated to these items proportionately.

⁴ Includes nursing care, services of other practitioners (osteopaths, naturopaths, chiropractors, faith healers, midwives), laboratory tests and X-rays, medical appliances and supplies, and ambulance service.

age, in 1955, as compared with \$60 in 1941 (table 1). When this is converted to 1941 dollars to eliminate the effect of the price change since that year, they are found to be buying a little more than twice as much in 1955 as in 1941. Moreover, this comparison of data for families understates the change in per capita expenditure since average size of farm families decreased from 4.0 to 3.8 persons in this period.

All the items of medical care have not shared equally in this gain. Health insurance appears to have made the greatest gain, although premiums paid cannot be measured precisely in dollars of constant purchasing power because there is no measure of the change in price of this item over the whole period. Consumption of medicines and drugs appears to have tripled. This increase is of particular interest since it might be expected that as the amount of medical care increased, there would be a decline in self-medication and therefore no more than a moderate increase in the volume of drugs bought. At least two factors have operated to increase expenditures. Dispensing of drugs by physicians has been decreasing over the past several decades, with a resulting increase in purchases. Also, the period since 1941 has been marked by the introduction of a wide range of antibiotics and other new drugs that are in a completely different price range from the old drugs. It is also possible that there was over-reporting of this item in 1955, although there is no conclusive evidence on this point.

The relative increases for the other major components of medical care were less than that for the category as a whole. If, however, instead of considering health insurance as a separate component, one-third of the premiums are assigned to physicians' services and two-thirds to hospital care, the volume of physicians' care used is found to have increased in almost the same proportion as all medical care, and the volume of hospital care to have made a greater increase.

While health insurance and medicines and drugs, the items that made large individual gains, account for more than 40 percent of the total increase, some of the items that made smaller gains also contributed substantially. Direct expenditures for physicians' services ac-

Methodology and Definitions

Data on medical expenses in 1955 were obtained as part of a survey of farm-operators' farm and family expenditures conducted jointly by the U. S. Department of Agriculture and the U. S. Bureau of the Census to provide a set of weights reflecting expenditure patterns of a recent year for use in calculating the parity index, and to improve the basis for estimating farm-operator production expenses (8). Because of the large number of items for which data were required, two national samples were used, data on production expenses being obtained from one and data on family living expenses and income from the other. In the sample providing data on family living expenses there were 3,985 families and single individuals.

In this survey, expenditures for medical care include health insurance premiums and dues to prepayment plans paid by the family, and expenses for the treatment of illness and routine physical and dental examinations incurred by the family in the schedule year and not covered by insurance. Ex-

penses were reported even though payment may not have been made within the schedule year.

The following differences in definitions relating to medical care exist between the various studies cited here:

In the 1950 and 1955 studies, vitamin and mineral preparations are classified as medicines and drugs, hence in medical care. In the earlier studies these items were considered to be food supplements and were classed with food. Inclusion of these preparations raises the average farm-family expenditures in 1955 from \$37 to \$43.

Expenditures for health insurance prepayment plans were not covered in the 1935-36 study. This disparity does not affect the comparability of the data materially since there was very little of this type of insurance at that time.

More detail on medical care expenditures from this survey will be available in forthcoming publications of the Department of Agriculture.

count for a fourth of the gain; although the relative increase in this item was below the average for medical care, the item was such a large component of the total in 1941 that even a moderate percentage increase resulted in a substantial increase in the total amount. Similarly, dental care, although showing a much less dramatic rise in expenditures than did health insurance, contributed almost as much as health insurance to the overall gain.

The prices of the components of medical care did not change equally over the period 1941-55. As measured by the consumer price index of the Bureau of Labor Statistics, the cost of services increased more than the cost of goods. The greatest price increase occurred in hospital rates.

As a result of price changes and differences in the volume of services and goods consumed, there have been changes in the distribution of the medical care dollar. Physicians' services, including those paid for directly and by insurance, are still the largest single component, but they have become somewhat less important, taking only 33 cents of the medical care dollar

instead of 38 cents. Dental care and eye tests and glasses also showed small losses in importance. The greatest change occurred in hospital care; the proportion of the medical care dollar spent for this item, either directly or through insurance, almost doubled.

Farm-Urban Comparisons

As was pointed out earlier, in 1950 urban families spent, on the average, \$65 per person for medical care. If between 1950 and 1955 they increased their spending in proportion to the increase shown by all United States consumers (and this is a reasonable assumption since they constituted almost two-thirds of all consumers in 1950), by 1955 they were spending \$81 per person. If this is so, in that year the level of spending of rural families (\$63 per person) was about 80 percent of that of urban families, whereas in 1941 it was less than 50 percent. The amount of money spent is not a precise measure of the volume of services received, since there may be a price differential between urban and rural areas.

The division of the medical care dollar between health insurance and prepayment plans on the one hand and direct expenditures on the other seems to be much the same in urban and farm families, but fewer farm families have the protection of insurance. In 1950, 64 percent of urban families reported premium payments and presumably in the 5 years between surveys this proportion increased somewhat, but in 1955 only 51 percent of farm families were making such payments. The average premium paid in 1955 by farm families carrying insurance was considerably larger than the average premium paid in 1950 by urban families with insurance: \$82 as contrasted with \$53. Although no direct comparison of coverage obtained is possible, it is readily apparent that the covered farm family has considerably less

protection than the covered urban family. The difference in premiums is barely enough to offset the price rise in the intervening years. Additional considerations are that fewer farm than urban families obtain their insurance in connection with employment and therefore fewer benefit from the contributions of employers, and that many farm families are not in a position to take advantage of group insurance plans and the savings they make possible.

Effect of Income and Other Factors

Income is an important determinant of expenditures since families cannot continuously spend beyond their resources. The expenditure data classified by income must be interpreted

Table 2. Medical care expenditures, by family income, farm-operator families and single farm operators, 1955

¹ Total money income as collected in this survey was subject to under-reporting, particularly for income from operation of the farm. The income distributions given here are not corrected for this under-reporting, but should nevertheless be useful for classifying families into homogeneous groups (with respect to 1955 income), for the presentation of expenditure data.

with the knowledge, however, that there was substantial under-reporting of income in this as in most surveys. Estimates of aggregate net farm income derived from the 1955 survey are as much as a third below estimates based on other data, but nonfarm income is in line with other estimates. Since the degree of under-reporting probably was not constant among all respondents, there is undoubtedly some error both in the absolute level at which some families are classified and in their relative positions in the income scale.

Average expenditures per person ranged from \$45 among families reporting incomes of \$250 to \$1,000 to \$100 among families with incomes of \$7,500 and over (table 2). Families in the lowest income class (under \$250) reported larger expenditures than those with somewhat higher incomes. Although it can be assumed that some of these families are misclassified as a result of under-reporting of income, it is also probable that some of them are in the lowest class because of temporary fluctuations in income. For the latter group, ill health may partly explain both their income position and the size of their medical care expenditures, but this can be only a minor factor as the same relationships can be observed in the total consumption expenditures and in those for other categories.

In the group with reported incomes under \$2,000, which included almost half of all farm families, medical care expenditures averaged \$55 per person or less. Those with reported incomes between \$2,000 and \$5,000, slightly more than a third, had per person expenditures averaging between \$60 and \$65. Expenditures rose rapidly among families with incomes of \$5,000 or more.

At all income levels, the proportion of families reporting some direct medical care expenditures was high, with only a slight tendency to increase with income. The proportion of families reporting expenditures for health insurance was considerably lower and was more closely related to reported income, rising with it. There was less variation with income in per person expenditures in the North Central region than in the South (table 2). Average per person expenditures in families with incomes below \$3,000 were lower in the South than in

the North Central States, but when incomes were \$3,000 or more southern families spent more per person.

Other characteristics than income are also of importance in determining expenditures. Frequently, however, these characteristics have systematic relationships among themselves and with income that make it difficult to show by means of simple tabulations such as those presented here which characteristics are most closely related to the variation. In table 3 expenditures by race, tenure, education of the operator, and family size are shown for all farm families and for families in a relatively narrow income band. In the latter group, much of the effect of variation in income is eliminated, but other internal relationships are not controlled. For example, nonwhite families are less likely to be in the owner class, they have lower educational attainment as a rule, and the families tend to be larger.

In the South, where 19 percent of all respondents were nonwhite, medical expenditures show a difference by race. In families with incomes below \$3,000, who constitute 85 percent of the nonwhite and 67 percent of the white respondents, medical care expenditures of nonwhite families tended to be about half those of white families of comparable income. Since nonwhite families are larger on the average than white families, the difference was even greater on a per person basis. Interestingly enough, white and nonwhite families carried some type of health insurance in about the same proportions, but the average premium or dues payment was smaller among nonwhite families. Race had a greater effect on expenditures for medical care than on total consumption expenditures. This may result from differences in facilities available to the two groups. It may also be the indirect effect of education, for in this study medical care expenditures tended to rise with an increase in the education of the farm operator.

Two different regional patterns appear when medical care expenditures are classified by income and tenure. In the North Central region, tenants consistently spent more than owners with comparable incomes. In the South, however, owners spent more than cash-and-share

small number of cases.

² Data not shown because of

tenants with the same incomes, and the latter in turn spent more than sharecroppers. The pattern in the North Central region seems to represent a break with the past. It may be related to the higher educational attainment of tenants in this region; they tend to be considerably younger than owners and therefore to have progressed further before they left school. It may, however, reflect current attitudes toward farm ownership and the choice between saving to invest in the farm and spending for current consumption. It is possible that the higher expenditures of tenants represent a choice on their part of higher consumption and postponement of farm ownership, and a choice on the part of the owners to build up their investment in the farm. In the South, it must be recognized that the pattern by tenure is strongly influenced by the racial pattern. The proportion of nonwhite operators is largest among sharecroppers and smallest among owners. The pattern of educational attainment is also the reverse of that in the North Central region; the higher the position on the tenure ladder, the further the group has gone in school.

For the farm population as a whole, expenditures per family increased with family size until the 3-person family was reached; they remained at a fairly constant level until the

6-person family was reached and then decreased among the largest families. This pattern, however, conceals sharp regional variation. In the North Central States the average expenditure tended to rise more or less consistently with family size throughout the entire range, while in the South it rose only until the three-person family was reached and dropped thereafter. In both regions there was a sharp increase in per person expenditures between the single individual and the two-person family; thereafter per person expenditures decreased with increase in family size.

Regional Comparisons

In 1955, medical care expenditures were lower among southern farm families than among those in the North Central region. This difference is due in part to lower income, lower educational attainment, and a higher proportion of nonwhites among the population in the South. That this is not the entire explanation, however, can be seen by comparing the expenditures of comparable groups in the two regions. At most income levels, southern families spent less than those in the North Central region (table 2). Furthermore, groups comparable as to tenure, education, or family size, in addition

¹ Not available.

to income, show a similar regional disparity (table 3). It is encouraging to note, therefore, that since 1945 expenditures have increased more in the South than in the North Central region. This can be attributed at least in part to a greater increase in income in the South and to a more than proportionate loss from the population of those groups whose expenditures are lowest—sharecroppers, other tenants, and non-white operators.

For most categories of medical care southern families spent less than North Central families (table 4). Only for medicines and drugs do they appear to spend substantially more. Direct expenditures for hospital care are somewhat higher, but when that proportion of insurance premiums assignable to hospital care is added to direct expenses, the total for northern families is higher. The higher expenditures of southern families for medicines and drugs, especially when occurring in conjunction with lower expenditures for physicians' care, seem to indicate a greater degree of self-medication.

The general patterns of expenditures in the two regions were similar. Such differences as were found, in line with the difference in amount of expenditures, indicate less care in the South. Fewer southern families had expenditures for dental and eye care, and smaller proportions of the medical dollar were spent on these items. Fewer southern families had direct expenditures for hospital care, and it probably follows that there were fewer hospital admissions. If health insurance premiums are assigned to the categories of care, expenditures for both hospital care and physicians' services were of greater importance in the North Central region than in the South. Since total medical expenditures were lower in the South than in the North Central region and expenditures for medicines and drugs were greater, it follows that a considerably larger proportion of the medical dollar went for medicines and drugs in the South.

This regional disparity is not confined to the farm segment of the population. In fact, per

person expenditures for medical care show that the relative position of the rural South is higher than that of the urban South:

	United States	South
Farm operators, 1955.....	\$63	\$57
Urban population, 1950.....	65	55

The urban South, however, has considerably less effect on the national average for the urban population than does the rural South on the national rural figure, since less than one-fourth of all urban families live in that region as compared with almost one-half of all rural families. If the South carried the same weight in both the urban and farm populations, much of the present difference between urban and rural expenditures would disappear.

Available data indicate an increase in body fat up to about age 50, with women gaining more than men. It is suggested that "the secret to a long life for a body pleasantly surfeited with fat may be found by studying older women."

Age Changes in Body Composition

OLAF MICKELSEN, Ph.D.

EVALUATION of age changes in the composition of the body is hampered by the inadequacy of current procedures for determining body composition. Although a number of techniques have been proposed, only a few of these have been validated by direct carcass analysis. Validation has been done only on experimental animals.

In order to simplify the problem of determining body composition, the body may be said to be composed of the skeleton, fat, and fat-free tissue (muscle). For any individual, the weights of the skeleton and of fat-free tissue appear to be fixed within relatively narrow limits. The weight of body fat, however, covers a relatively wide range.

The methods used in determining body composition provide, at best, estimates of the size of either the fat or fat-free tissue. Either one or both of these components may be measured, but usually only one is determined. The mathematical equations that have been developed for computing the percentage composition of the body contain factors that make allowances for the weight of the skeleton. Minerals are one of the chief components of the skeleton, but since minerals account for a relatively small percentage of the body weight, any variation in the size of this component will have only a minor influence on body composition.

Dr. Mickelsen is chief of the Laboratory of Nutrition and Endocrinology, National Institute of Arthritis and Metabolic Diseases, Public Health Service.

Although it would be desirable to know the changes that occur with age in all body components, most of the work in the field of body composition has been concentrated on determination of the amount of fat. This stems from the interest engendered during the past few years in obesity in general. Changes in the skeletal mass have been largely neglected.

On the basis of clinical experience it has been proposed that changes do occur in the skeletal mass. Many clinicians working in the field of geriatrics are impressed by the fragility of the bones in their older patients. This has been assumed by some to be due to a negative calcium balance, with a consequent depletion of bone minerals. However, a recent study suggests that "the onset of bone fragility in the aged is a composite effect of many factors and is probably more intimately related to endocrine changes, decreased activity, and loss of muscle tone than to level of nutrition" (1).

Methods of Determining Body Composition

A brief review of some of the procedures proposed for determining body composition will give some idea of the limitations and difficulties in this field. Although there are a number of methods for estimating the composition of the body, none of them is ideal. Each procedure has its limitations. The method that has been used most frequently as a reference or standard is the densitometric technique based on weighing the individual under water.

Because of its simplicity, comparison of the individual's height and weight with values listed in standard tables is probably the most commonly used procedure for obtaining crude estimates of body fatness, and thus, indirectly, of body composition.

Standard Height-Weight Tables

The height-weight tables most often used for evaluating body fatness are those compiled by the Association of Life Insurance Medical Directors on the basis of medical examinations performed on individuals applying for insurance during the years 1885 through 1910 (2). One of the most serious limitations in using these tables is the absence of a correction factor for the clothing and shoes worn by the individuals who were weighed (3). Another limitation is the disagreement as to the deviation in weight that must occur before an individual is considered obese. Values ranging from 5 to 20 percent have been proposed as the upper range of "normal" body weight for any height.

These tables make no allowance for variation in body build. Keys and Brozek (4) have shown that the variation in body build could be illustrated by the data of Munro (5). Munro found that the groups of selective service registrants of the same age and stature who had chest circumferences of 32, 37, and 42 inches had average weights of 130, 158, and 198 pounds, respectively. In general, the heaviest men had the largest body frames; yet the height-weight tables suggested only one weight (150 pounds) for individuals of this height. When compared with the values in the table, the men with the largest body frames would be as much as 36 percent overweight. That all of the heaviest men were not obese is suggested by the work of Welham and Behnke (6). Using the densitometric technique (described below), they found that professional football players who were in peak physical condition were 20 or more percent overweight according to the standard height-weight tables. However, on the basis of body density, these "overweight" men had very little fat in their bodies. If obesity is defined as a condition in which there is a surplus of body fat, these men obviously were not obese.

Subcutaneous Fat Determinations

Body fat has also been estimated from the thickness of skinfolds on various parts of the body. The skinfold is "lifted up" with the fingers from the underlying muscle. A variety of calipers are available for quantitating these measurements. This procedure is based on the observation that in man a large proportion of the total body fat is found in the subcutaneous tissue (4).

Unfortunately, there are practically no data on human beings to indicate the relative distribution of fat throughout the body in the lean and the obese. X-ray evidence is available for rats which became obese as a result of an ad libitum consumption of a high-fat diet (7). These rats, compared with their littermates fed a low-fat diet, showed a tremendous increase in the amount of fat in the subcutaneous area (see illustration). Associated therewith is a marked increase in the amount of fat in the abdominal cavity. The lean rat shows a proportionately smaller amount of fat, not only in the subcutaneous areas but in the abdominal cavity as well. Comparable data for guinea pigs have been presented by Pitts (8). The mass of the subcutaneous fat in the guinea pig was almost directly proportional to the total body fat.

The most extensive evaluation of the skinfold-thickness method for determining body fat has been made by Keys and Brozek (4). In their study the skinfold thickness at a number of sites on the body was determined for a large number of subjects. At the same time, total body fat in each subject was estimated by the densitometric method. On the basis of these measurements equations were developed for estimating the body fat from the skinfold thickness (9). Similar work has been done by Pascale and others (10, 11). The equations provide values which at best only approximate the body fat content as calculated from body density. A partial explanation for the inconsistent body fat values derived from the skinfold measurements stems from the finding that there is considerable individual variation in the distribution of subcutaneous fat throughout the body (4).

A few attempts have been made to determine the amount of fat in the body from X-rays of

X-rays of lean and obese littermate rats.

selected areas. Stuart and co-workers (12, 13) have used X-rays of the antero-posterior view of the right leg at the maximal width of the calf. These studies were confined largely to children. Reynolds (14) has extended this technique to the study of adults. He reported that the ratio of thickness of adipose tissue to bone width of the leg is much greater in women than in men. The ratio decreases with age in men but increases in women.

A recent report by Garn (15) on the fat content of adults as determined by X-rays suggests that there is very little difference in the absolute amount of fat in men and women. Since the body weights of the women were considerably lower than those of the men (58.3 as compared with 76.4 kilograms), the percentage differences in fat content were significant. Garn found that the average weight of fat in 107 healthy American women ranging in age from 20 to 60 years, with a mean of 39 years, was 13.7 kilograms, while that in 81 men in the same age

range was 12.6 kilograms. The fat content of the women was 23.7 percent, for the men 16.8 percent.

Densitometry

A procedure that has been studied rather extensively during the past few years determines body density and, from this, the relative composition of the body. The difference in density of body fat and the fat-free residue is great enough to permit calculating the amount of fat in the body from the body's density. This density has been determined by two different methods.

One method of determining body density is based on weighing the subject under water. This procedure received its greatest stimulation as a result of the studies of Behnke and co-workers (16). The technique is fraught with difficulties. The primary one is the inability of readily determining the residual air and the air that may be retained in the gastrointestinal

tract at the time of the underwater weighing. Body density can be corrected for residual air, but to do it accurately would make the determination both cumbersome and time-consuming. A standard correction cannot be made for residual air since there is considerable variation among individuals, as well as an increase in the absolute residual air volume with increasing age (4). A second difficulty is trying to weigh under water an individual who has any fear of being submerged. The latter is likely to be important with older people, especially those who have never learned to swim.

The other method for determining body density involves measurement of the body's volume. The volume of the body can be calculated by the displacement of helium in a chamber of known volume. This method has been used by Siri (17) for human beings and by Walser and Stein (18) for animals.

Theoretically, the gas-displacement technique should be far superior to the underwater-weighing procedure since any air in the lungs at the time of measurement should have practically no influence on the density. The anxiety associated with the method should be minimal. To what extent this modification of the densitometric method will be used is at present hard to predict.

Wedgewood and Newman (19) modified the Drinker respirometer so that the volume of the subject can be calculated from the changes in pressure associated with the pulsations of the bellows. The sensitivity and applicability of this technique have yet to be assayed.

Body Water

There are many data showing that in normal animals the relation between the amount of water and the amount of protein is fairly constant (20). The fat-free weight of the body can be calculated on the basis of this relationship. Since the minerals represent only a small fraction of the body (21, 22), slight variations in this component have a negligible effect on the results. The difference between the body weight of the individual and the calculated value for fat-free body tissue represents the weight of body fat.

A number of substances, such as urea, thiourea, deuterium oxide, tritium oxide, anti-

pyrine, and acetylamino-pyrine, have been used in estimating body water. (For discussion of the various techniques and references thereto, see reference 4). A known amount of the substance is given by mouth (urea) or injected intravenously (the other substances). Blood samples are taken at intervals and analyzed for concentration of the injected substance. Total body water content can be calculated from the concentration of the substance in the blood at the different time intervals and the amount of the substance given. All the methods require from 1 to 3 hours for uniform distribution of the compound throughout the body water. The procedures necessitate all the care and safety precautions used in any intravenous therapy.

There are a number of situations in which the relationship between body water and protein deviates from the usual ratio. In most of these cases, especially those associated with edema, the abnormality is due primarily to a marked increase in the extracellular fluid. By determining the volume of the extracellular fluid as well as total body water, a correction can be made for the abnormal hydration. Recent work indicates that the extracellular fluid space as measured with thiocyanate decreases steadily from a little more than 40 percent in infancy to a constant value of 23 percent in adulthood (23).

Fat Solvents

Cyclopropane has been used at New York University for estimating the amount of fat in the body directly in studies with rats (24). The air the animal inhales contains a known amount of cyclopropane. The volume of gas retained in the body is proportional to the amount of fat in the body. So little has been done with this procedure, however, that it is difficult to evaluate its applicability and usefulness in studies with man.

Factors Influencing Body Composition

There is surprisingly little factual information on the changes that occur in the human body as it grows older. All of the studies have compared young individuals with older people. Since so many years separate a man's youth

from his old age, it is doubtful whether there will ever be any extensive longitudinal studies on adults to bridge the present gap.

Influence of Age

The height-weight tables of the Association of Life Insurance Medical Directors indicate that a half century ago both men and women continued to increase in weight even though there was no change in height as they became older (2). Changes comparable to these are still occurring. Recent data show that from age 25 to 60 years men in the United States who are 67 inches tall gain 8 percent in weight, while women of the same ages who are 63 inches tall gain 15 percent (25-27).

It has frequently been assumed that the increase in body weight with age is primarily, if not solely, due to an increase in body fat. Evidence for this assumption has been presented by Brozek (28), who compared a group of young men (18-25 years) with older men (45-54 years). Although the average heights for the two groups were the same, the older men were, on an average, 11 pounds heavier than the younger men. Underwater weighings corrected for residual air at the time the weights were recorded showed that the younger men had 14 percent fat in their bodies while the older men had 24 percent.

The increase in body fat associated with the increase in body weight that accompanies the aging process is accentuated by the apparent replacement of a certain portion of muscle mass with fat, according to evidence adduced by Brozek (28). Thirty-three young men (22 through 29 years) and an equal number of older men (48 through 57 years) were matched for height and weight. Specific gravities indicated that although there was no difference in height or weight between the two groups, the younger men had 16 percent fat in their bodies while the older men had 23 percent.

Influence of Activity

Physical activity, especially if it is strenuous, is associated with a marked reduction of body fat even though the body weight may be considerably in excess of the "standard" as listed in height-weight tables. Welham and Behnke (6) emphasized this point in their studies with

younger men. Brozek (28) and Brozek and Keys (29) found a similar situation among older men. The physically active men were seven pounds heavier than the inactive men even though the heights were the same in both groups. However, the heavier body weights were associated with a lower body fat content (24 percent as compared with 27 percent).

Males vs. Females

Garn and Harper (30) have studied the distribution of fat in males ranging in age from 20 to 69 years by means of roentgenograms. Thickness of the subcutaneous fat over the iliac crest showed the greatest increase with age. Fat in the trochanteric and deltoid regions also increased, but to a lesser extent than that in the iliac region. There were no measurable changes in the thickness of the adipose tissue on the anterior surface of the leg and the middle area of the lower arm. On the basis of the amount of fat in the trochanteric area, Garn and Harper estimated that the body fat increased from 16 percent in younger men to 22 percent in older men. These values are similar to those reported by Brozek (28).

For women the total body fat increased from 26 percent at age 25 to 38 percent at age 55, as shown in the tabulation. These values were for women whose body weights were, on an average, from 95 to 97 percent of those listed in the standard height-weight tables (31). When these values are compared with those for men equally lean according to the standard height-weight tables, it is obvious that the body fat content of women is much greater than for men at each age group.

Age (years)	Total body fat (percent)	
	Men	Women
25 -----	13.1	26.5
35 -----	17.3	30.5
45 -----	21.6	34.5
55 -----	25.9	38.5

NOTE: Percentages were calculated using a linear prediction equation based on the least square fit of the values obtained by the densitometric method corrected for residual air (31).

In women, the increase in body fat with age is associated with an increase of the fat in the abdominal area (32). Since this conclusion

was based on skinfold measurements, it was not possible to determine whether the increase in inner fat was due to the fatty infiltration of the organs. There was little change in the skinfold thickness of the extremities with age in women, but there were marked changes in the thickness of subcutaneous fat on the chest, side, waist, and back.

Edwards (33) determined the skinfold thickness in 53 areas of the body in males and females ranging in age from 5 to approximately 50 years. He found that the distribution of fat in the different parts of the body was the same in both sexes before puberty. After puberty, women had about 1.2 times as much fat on their legs, in proportion to the total amount of subcutaneous fat, as men. In all groups, the women had approximately 1.7 times as much fat in the subcutaneous areas as the men. It is difficult to determine from these data any absolute changes that occur with age.

Conclusion

Factual data on body composition are notably scarce. What we have indicate an increase in body weight up through approximately age 50 and a decrease thereafter (28). There are no data which indicate that the weight of the individual decreases after age 55.

The difficulty with the reported body weights of older people is the impossibility of determining whether the decrease in weight is due to the earlier deaths of the heavier individuals or represents an actual loss of weight with age. Although there is an increasing body of data from longitudinal studies of children, such information is woefully lacking for adults, especially for individuals over 60 years of age. Only longitudinal studies permit determination of the actual changes that occur with age.

Few studies bear upon changes in body composition occurring in women with the passage of time. The prominent attention that obesity has received during the past few years would make such studies desirable. The work of Skerjil and others (32) indicates that in older women of "standard" weight, more than one-third of their body is fat. Even under that "stress," if it is stress, women outlive men by a significant number of years. This suggests that

the secret to a long life for a body pleasantly surfeited in fat may be found by studying older women.

Course in Control of Foodborne Diseases

A multidiscipline course in epidemiology and control of foodborne diseases will be offered at the Communicable Disease Center, Public Health Service, Atlanta, Ga., May 19-23, 1958.

The course is designed for physicians, veterinarians, nurses, nutritionists, dietitians, laboratory workers, environmental health supervisors, and other members of the public health team. Preference will be given to persons whose work concerns application of epidemiological techniques in this field.

Further information and application forms may be obtained from the Chief, Communicable Disease Center, Public Health Service, 50 Seventh Street, NE., Atlanta 23, Ga. Attention: Chief, Training Branch.

Poisonous Fishes

BRUCE W. HALSTEAD, M.D.

MAN'S KNOWLEDGE of poisonous fishes dates back to ancient times. At least one of the Mosaic laws is believed to have been aimed directly at eliminating poisonous fishes from the Israelite diet, "These ye shall eat of all that are in the waters: all that have fins and scales shall ye eat: And whatever hath not fins and scales ye may not eat: it is unclean unto you" (Deuteronomy 14: 9-10). The French archeologist Claude Gaillard reported that hieroglyphics and figures of the deadly *Tetraodon lineatus* appear frequently on ancient Egyptian tombs (1), and according to the Egyptologist Keimer, this scaleless species was recognized as poisonous during the time of the Pharaohs. Galen is said to have reported in his *De Alimentis* that the flesh of the moray is dangerous to eat (2). Alexander the Great forbade his soldiers to eat

fish during conquests because he believed that some species produced skin disorders.

Peter Martyr, the first historian of the West Indies, made the earliest reference to ciguatera in 1555 (3). In de Landa's famous *Relacion de Las Cosas de Yucatan*, written in 1566, the lethal qualities of puffers are mentioned (4).

Beginning with the 19th century, hundreds of publications appeared on the subject of fish

Dr. Halstead is generally regarded as the world's leading authority on poisonous fishes. He is chairman of the section of natural products, School of Tropical and Preventive Medicine, College of Medical Evangelists, Loma Linda, Calif. Until July 1, 1958, he is on military leave with the Division of Preventive Medicine, Naval Medical School, National Naval Medical Center, Bethesda, Md.

poisoning, including some comprehensive reviews and bibliographies (3, 5-11).

Because of their somewhat sporadic and unpredictable appearance, generally affecting only small numbers of persons at any one time, poisonous fishes have not attracted a great deal of attention in medical circles. However, the public health significance of poisonous fishes was pointed up in the series of outbreaks which occurred in Midway, Johnston, and the Line Islands, beginning about 1943 and reaching a peak about 1946 (12, 13).

Recent mass intoxications in the western Pacific have once again directed attention to the public health importance of poisonous marine organisms. These outbreaks began about 1952, became increasingly severe during 1955, and have continued until the present time, intoxicating a number estimated at more than 40,000 persons. The bulk of the outbreaks have taken place in Japan, the Philippine Islands, and more recently in Viet Nam. The causative agents were octopus, *Octopus vulgaris*, *O. dofleini*, squid, *Omnastrephes sloani pacificus*, Jap-

anese horse mackerel, *Trachurus japonicus*, common Japanese mackerel, *Scomber japonicus*, flying fish, *Prognichthys agoo*, and oceanic bonito, *Katsuwonus pelamis*. All of the outbreaks have been seasonal, taking place during June to the middle of September. Bacteriological tests have been negative, and the degree of freshness of the organisms seems to have no bearing on the matter. The symptoms are similar to those produced by bacterial food poisoning, but no human pathogens have been isolated by Japanese epidemiologists. The mortality rate in the largest series of Japanese fish outbreaks in 1955 was 0.77 percent (14).

According to a report received from the Bureau of Fisheries of the Philippine Government, another series of outbreaks of fish poison-

Some fishes associated with ciguatera are illustrated across the top of these pages. They are: 1. Triggerfish, *Odonus niger*. 2. Wrasse, *Epibulus insidiator*. 3. Jack, *Caranx melampygus*. 4. Surgeonfish, *Acanthurus triostegus*. 5. Snapper, *Monotaxis grandoculis*. 6. Seabass, *Variola louti*. 7. Grouper, *Cephalopholis argus*. 8. Red Snapper, *Lutjanus vaigiensis*.

ing took place in April 1957. The complete number of persons involved has not been determined as yet, but several deaths have been reported. The causative agent in most of the Philippine poisonings has been the oceanic bonito, *K. pelamis*. Philippine public health authorities are establishing regulations prohibiting the sale of the oceanic bonito in some localities. Some intoxications from fishes have been reported in Viet Nam, but as yet no details are available as to the nature of the outbreaks.

Since intoxications resulting from poisonous fishes are frequently confused with a variety of other ailments, a review of the epidemiological and clinical aspects of the problem of ichthyosarcotoxism is timely. The chemistry of these poisons has been reviewed elsewhere (31).

Epidemiology

Judging from the public health and toxicological reports that have appeared to date, any marine fish can under certain circumstances become poisonous as a result of its food habits. Toxicity is not species specific, except possibly in puffers or tetraodontoid fishes. More than 300 species of marine fishes have been incriminated as causative agents in producing human intoxications of the ciguatera type alone. Most poisonous fishes are shore forms rather than oceanic inhabitants. Fishes captured in deep waters far from shore are generally safe to eat. Some of the more common families of marine fishes which have caused human intoxications are listed under the various clinical types of fish poisoning.

Poisonous fishes are largely circumtropical in distribution, but on occasion occur in temperate waters. With the exception of 2 or 3 boreal species they are currently believed to have a maximum distributional range of 45° north and 45° south of the Equator. Particularly large populations of poisonous fishes are known to occur in the central Indo-Pacific area and in the West Indies. They are more common near islands than along continental shores. Within these general areas, poisonous fishes seem to be quite circumscribed in distribution. They may vary considerably in their distribution about a single island. A species may be toxic in one

part of the island, but edible in another. Lagoon fishes are more likely to be poisonous than those living on seaward reefs.

The toxicity of puffers or tetraodontoid fishes generally follows closely their reproductive cycle. The toxin content of the fish is greatest just prior to spawning. For most puffers, spawning takes place during late spring or early summer. Toxin content is lowest during fall and winter. There is some evidence that the barracuda (*Sphyræna* spp.) may follow a similar, but less pronounced, seasonal pattern. However, in most other species there is no evidence of a seasonal fluctuation.

The poison in tetraodontoid fishes is usually more concentrated in the liver, gonads, and skin, but other parts of the viscera may also be toxic. Puffer musculature is generally non-poisonous. The distribution of poison is exceedingly variable in other kinds of fishes. If a fish is toxic, the musculature will be found to be poisonous in about 50 percent of the specimens, and the viscera, in about 90 percent or more. However, the distribution of the poison in the body of the fish varies from one individual to the next.

No consistent pattern has been observed as to the relationship between the size of the fish and its toxicity. It has been observed that unusually large specimens of jacks (*Caranx* spp.), grouper (*Epinephelus* spp.), and barracuda (*Sphyræna* spp.) are more likely to be toxic than smaller specimens. This has not been found to be necessarily true in other species.

Aboriginal peoples have numerous methods by which they attempt to distinguish a poisonous fish from an edible one. The significance of color change in silver coins, color of the fish, condition of the gills, position of the scales, ad infinitum, is generally without scientific foundation. To the best of our knowledge, one cannot detect a poisonous fish by its appearance. The most reliable field method is to feed a small sample of the fish to a kitten or a dog. If the animal remains asymptomatic for 12 hours, the fish is generally safe to eat. Investigations are currently in progress at the School of Tropical and Preventive Medicine, Loma Linda, Calif., with the hope of developing a reliable rapid chemical field test.

Origin of the Poison

The origin of ichthyosarcotoxins in nature has been the subject of much speculation and folklore. Numerous theories have been propounded, but few have any scientific basis (15, 16). It is certain, with the single exception of scombroid poison, the poisons are not bacterial in origin. Putrefactive processes do not play a part in the production of fish poisons. There is no evidence of any relationship between the presence of ichthyosarcotoxins and radioactive substances in the water. It is believed that most of these poisons are derived from the food which the fish eats. Food probably plays an important role in the direct production of even puffer poison.

The most widely accepted theory propounds the idea that the toxic substances, or their precursors, are obtained directly from marine littoral algae. It is doubtful that plankton play any role in the mechanism. Herbivores feed on the plants. Carnivores feed on the herbivores and man may become poisoned from eating either of them. Stomach content analyses have revealed that algae are more frequently present in poisonous fishes than any other types of food (17), and toxicological tests of these algae have shown some of them to contain toxic substances (18). Moreover, controlled laboratory feeding tests demonstrate that it is possible to induce toxicity in carnivorous species without evidence of detrimental effects on the fish, by feeding them toxic fish flesh. Further chemical and stomach analyses will be required before the toxin-food chain theory can be definitely established. Experimental work in attempting to determine the origin of fish poisons in nature is currently in progress by the author.

The incidence of fish poisoning cannot be accurately determined since the disease is frequently misdiagnosed and generally unreported. In the past, several hundred cases of puffer poisoning were reported each year in Japan, during some years accounting for as much as 44 percent of all fatal cases of food poisoning in that country. Japanese public health authorities state that puffers continue to be their greatest single cause of food fatalities (19, 20). Probably the second most common

type of fish poisoning is ciguatera. Third on the list would be scombroid poisoning, with the other forms of fish poisoning being relatively uncommon. It is unfortunate that there are so few reliable statistical data available. Local public health authorities should encourage the reporting of outbreaks, since poisonous fish may constitute a serious public health and economic threat in some regions.

Recent biotoxicological surveys that have been conducted in the tropical Pacific give some idea as to the incidence of poisonous fishes in specific localities.

Locality	Number species tested	Percent of species found toxic
Phoenix Islands (16) ---	93	29
Johnston Island (16) ---	60	75
Galapagos Islands (29) -	57	67
Cocos Island (30) -----	33	67

Among important field studies (7, 8, 21-23), Hiyama's work (7) is particularly useful, magnificently illustrated, and contains a valuable review of the poisonous fish problem in Saipan and the Marshall Islands. Only meager statistical data are contained in any of these reports, but they do aid in developing an appreciation of the scope of the problem in the regions discussed.

Clinical Characteristics

Since the chemical characteristics of fish poisons have not been defined, poisonous fishes may be tentatively classified on the basis of their phylogenetic relationships and symptomatology of the intoxications which they produce (10, 24). Certain fish groups are classified under more than one category. Although the weaknesses of this somewhat artificial system are recognized, it appears to be the most practical classification at present. Forms of ichthyosarcotoxism caused by fishes may be subdivided into the following clinical categories (see table).

Lamprey and Hagfish Poisoning

The slime and flesh of certain lampreys and hagfishes are reported to produce a gastrointestinal upset (32). The clinical characteris-

Diagnostic characteristics of the various types of ichthyosarcotoxism

Type of poisoning	Causative fish	Symptomatology
Lamprey or hagfish-----	Lampreys, hagfish (slime, flesh).	Gastrointestinal upset(?). Precise symptomatology unknown.
Elasmobranch-----	Sharks, rays (liver, flesh)-----	Gastrointestinal symptoms predominate in mild cases; neurological symptoms in severe cases. Deaths reported, but case fatality rate unknown.
Chimaeroid-----	Chimaeroid or ratfish (flesh, viscera).	Neurological symptoms(?). Precise symptomatology unknown.
Gymnothorax or moray eel.	Moray eels (flesh, viscera)-----	Violent with convulsions and paraly. Case fatality rate about 10 percent or more.
Scombroid-----	Scombroid fishes—tuna, bonito, skipjack, etc. (inadequately preserved flesh).	Histamine-like reaction with nausea, vomiting, flushing of the face, swelling of the lips, urticaria, and pruritus. Symptoms subside usually within 12 hours. Antihistaminic drugs effective.
Puffer-----	Tetraodontoid or puffer-like fishes (viscera).	Rapid onset and extremely violent neurotoxic symptoms: paresthesias, motor paralysis, convulsions, death by respiratory paralysis. Case fatality rate about 61 percent.
Ciguatera-----	More than 300 species of tropical reef fish, including snapper, seabass, grouper, barracuda, wrasse, parrotfish, and surgeonfish.	Onset may be gradual or sudden. Symptoms mild to severe. Gastrointestinal and neurotoxic. Paresthesias, extreme weakness, joint aches, myalgia and paradoxical sensory disturbance predominate. Case fatality rate about 7 percent.
Gempylid diarrhea-----	Gempylids, escolar (flesh)-----	Diarrhea develops rapidly but is painless. No other untoward effects.

tics of the intoxication, termed lamprey and hagfish poisoning, have not been completely defined.

Elasmobranch Poisoning

The most severe cases of elasmobranch poisoning usually result from the ingestion of the liver of sharks and rays. The musculature of some elasmobranchs is also reported as mildly toxic with the symptoms seldom more than that of a mild gastroenteritis with a predominating diarrhea. Ingestion of toxic liver results in the onset, usually within a period of 30 minutes, of nausea, vomiting, diarrhea, abdominal pain, headache, a rapid, weak pulse, malaise, cold sweats, oral paresthesia, a burning sensation of the tongue, throat, and esophagus. As time progresses, the neurological and other symptoms become more pronounced, resulting in extreme weakness, trismus, muscular cramps, sensation of heaviness of the limbs, blepharospasm, dilatation of pupils, hiccups, visual disturbances, joint aches, delirium, ataxia, incon-

tinence, dysuria, respiratory distress, coma, and death. The recovery period, if the victims recover, varies from a day or two to several weeks. The mortality rate is not known.

Chimaeroid Poisoning

The musculature and viscera of certain chimaeroids or ratfish have been incriminated as containing a neurotoxin. This form of ichthyosarcotoxism, if it occurs, would be termed chimaeroid poisoning. Only vague references have appeared in the literature regarding the toxicity of this group of fish, by Pellegrin in 1899, and by Phisalix in 1922. Halstead and Bunker reported in 1952 that the reproductive organs were toxic. Nothing is known about the nature of the toxin, or its relationship to other forms of ichthyosarcotoxism.

Moray Eel Poisoning

The musculature and viscera of some of the tropical marine muraenid or moray eels con-

tain a violent poison. The disease is termed gymnothorax or moray eel poisoning (25, 26). Symptoms of tingling and numbness about the lips, tongue, hands, and feet, with a feeling of heaviness in the legs, usually develop within several minutes to 8 hours after ingestion of the toxin. These symptoms may be followed by nausea, vomiting, diarrhea, abdominal pain, malaise, metallic taste, sore throat, laryngeal paralysis, meningismus, laryngeal spasm, aphonia, excessive mucus production, foaming at the mouth, intense perspiration, increased body temperature, crying out as if in pain, conjunctivitis, paralysis of the respiratory muscles, ataxia, general motor incoordination, trismus, violent clonic and toxic convulsions, abnormal deep and superficial reflexes, coma, and death. Sensory reactions to deep and superficial pain are usually normal. Characteristic signs of this form of intoxication appear to be the absence of thoracic respiration with pronounced abdominal breathing, profuse perspiration, violent convulsions, purposeless movements, and the extended period of time

Moray eel, *Gymnothorax javanicus*

in which areflexia is present. In some cases the reflexes may be absent for a period of 2 months or more. The case fatality rate is estimated to be about 10 percent, and death is believed to be the result of respiratory paralysis.

Scombroid Poisoning

Some of the scombroids (tuna, skipjack, and bonito) may on rare occasions cause ciguatera, but usually they produce an entirely different form of intoxication, termed scombroid poisoning. This is the only type of fish poisoning in which bacteria appear to play an etiological role in the formation of the toxin. If scombroids are inadequately preserved, a toxic "histamine-like" substance is formed, possibly from the decarboxylation of histidine, a normal consti-

uent of fish flesh. Kawabata and associates have recently termed this substance "saurine" (33). Victims complain of fish having a "sharp or peppery" taste. The symptoms most often present are nausea, vomiting, flushing of the face, intense headache, epigastric pain, burning of the throat, difficulty in swallowing, thirst, pruritus, swelling of the lips, and urticaria, which are typical of a histamine reaction. Symptoms generally subside within 12 hours.

Tuna, *Neothunnus macropterus*

For some unknown reason scombroid fish appear to be more prone to producing intoxications of this type than other fish. The mortality rate is unknown.

Puffer Poisoning

The most violent form of fish poisoning is produced by tetraodontoid or puffer-like fishes. The disease is characterized by rapidly developing, violent symptoms. The onset and symptoms in puffer poisoning vary according to the person and the amount of poison ingested. However, malaise, pallor, dizziness, paresthesias of the lips and tongue, and ataxia most frequently develop within 10 to 45 minutes after ingestion of the fish, but cases have been reported in which the symptoms did not develop for 3 hours or more. The paresthesias which the victim usually describes as a "tingling or prickling sensation" may subsequently involve the fingers and toes, then spread to other portions of the extremities, and gradually develop into severe numbness. In some cases the numbness may involve the entire body, in which instance the patients have stated that it felt as though their bodies were "floating." Hypersalivation, profuse sweating, extreme weakness, precordial pain, headache, subnormal temperatures, decreased blood pressure, and a rapid, weak pulse usually appear early in the succession of symptoms.

Gastrointestinal symptoms of nausea, vomiting, diarrhea, and epigastric pain are sometimes present early in the disease, whereas in other cases they are totally lacking. Contradictory statements appear in the literature relative to pupillary changes, but these differences can probably be resolved on the basis of the time at which the examination is made. Apparently the pupils are constricted during the initial stage and later become dilated. As the disease progresses the eyes become fixed and the pupillary and corneal reflexes are lost.

Shortly after the development of the paresthesias, respiratory symptoms become a prominent part of the clinical picture. Respiratory distress, increased rate of respiration, movements of the nostrils, and diminution in depth of respiration are generally observed. Respiratory distress later becomes very pronounced, and the lips, extremities, and body become intensely cyanotic. Petechial hemorrhages involving extensive areas of the body, blistering, and subsequent desquamation have been reported. Severe hematemesis has also been known to occur. Muscular twitching, tremor,

occurs, it generally takes place within the first 6 hours, or within 24 hours at the latest. The prognosis is said to be good if the patient survives for 24 hours.

Ciguatera

More than 300 species of marine fish have been incriminated as causative agents of this form of ichthyosarcotoxism. Fish most commonly involved are seabass or grouper, barracuda, snapper, parrotfish, wrasse, surgeonfish, and various other types of reef fishes.

The time of onset and symptomatology of ciguatera varies greatly according to the person, species of fish, toxicity, and amount and portion of fish ingested. Tingling about the lips, tongue, and throat followed by numbness may develop immediately or at any time within a period of 30 hours after the ingestion of the toxin. The usual time interval for the development of symptoms is from 1 to 6 hours. The initial symptoms in some instances consist of nausea, vomiting, metallic taste, dryness of the mouth, abdominal cramps, tenesmus, and diarrhea, followed by perioral tingling and numbness. The muscles of the mouth, cheeks, and jaws may become drawn and spastic with a feeling of numbness. Generalized symptoms of headache, anxiety, malaise, prostration, dizziness, pallor, cyanosis, insomnia, chilly sensations, fever, profuse sweating, rapid weak pulse, weight loss, myalgia, and joint aches are frequently present. Victims usually complain of a feeling of profound exhaustion and weakness. The feeling of weakness may become progressively worse until the patient is unable to walk. Muscle pains are generally described as a dull, heavy ache, or cramping sensation, but on occasion may be sharp, shooting, and affect particularly the arms and legs. Victims complain of their teeth feeling loose and painful in their sockets.

Visual disturbances, consisting of blurring, temporary blindness, photophobia, and scotoma, are common. Pupils are usually dilated and the reflexes diminished. Frequently reported are skin disorders, which are generally initiated by an intense generalized pruritus, followed by erythema, maculopapular eruptions, blisters, extensive areas of desquama-

Puffer, *Arothron meleagris*

and incoordination become progressively worse and finally terminate in an extensive muscular paralysis. The first areas to become paralyzed are usually the throat and larynx, resulting in aphonia, dysphagia, and later complete aphagia. The muscles of the extremities become paralyzed and the patient is unable to move.

As the end approaches, the eyes of the patient become fixed and glassy, and convulsions may occur. The victims may become comatose, but in most instances they retain consciousness and their mental faculties remain acute until shortly before death. Death results from a progressive ascending paralysis involving the respiratory muscles. On the basis of Japanese statistics, the case fatality rate is 61.5 percent. If death

tion—particularly of the hands and feet—and occasionally ulceration. There may also be a loss of hair and nails.

In severe intoxications, the neurotoxic components are especially pronounced. Paresthesias involve the extremities, and paradoxical sensory disturbances may be present in which the victim interprets cold as a "tingling, burning, dry-ice or electric-shock sensation," or hot objects may give a feeling of cold. In regard to the paradoxical sensory disturbance, the classical case usually cited is that in which an American naval officer who was poisoned by eating an amberjack was later observed subconsciously blowing on his ice cream, which was "burning" his tongue, in order to cool it. Ataxia and generalized motor incoordination become progressively worse. The reflexes are diminished and muscular paralyses develop. There may be clonic and tonic convulsions, muscular twitchings, tremors, dysphonia, dysphagia, coma, and death by respiratory paralysis. The limited morbidity statistics show a case fatality rate of about 7 percent. Death may occur within 10 minutes, but generally requires several days.

In those instances in which the victim survives, recovery is slow and convalescence may be very prolonged, with extreme weakness, sensory disturbances, and excessive weight loss being the last symptoms to disappear. When patients have survived severe intoxication, complete recovery has required a period of several years. Several workers have reported cases in which the symptoms persisted for as long as 25 years. Individuals who have been severely intoxicated have stated that during periods of stress, fatigue, exposure, or poor nutrition, there is a recurrence of the myalgia and joint aches similar to those suffered during the original acute period of the disease (10).

Gempylid Diarrhea

Some of the gempylids or escolaras contain an oil within their flesh and bone marrow which has a pronounced purgative effect when ingested. Gempylid diarrhea (27) develops rapidly, and is said to be without cramping or pain. Since there are no other untoward effects, ingestion of the oil can hardly be con-

sidered as an intoxication in the usual sense of the word.

Treatment of Fish Poisoning

The treatment of fish poisoning is largely symptomatic. There are no specific antidotes, and an attack does not impart immunity. Gastric lavage and catharsis should be instituted at the earliest possible time. In many instances, 10 percent calcium gluconate given intravenously has given prompt relief, whereas in others it has been ineffective. Paraldehyde and ether inhalations have been reported to be useful in controlling the convulsions. Nikethamide or one of the other respiratory stimulants is advisable in cases of respiratory depression. In cases where excessive mucus production is a factor, aspiration and constant turning are essential. Atropine has been found to make the mucus more viscid and difficult to aspirate, and is not recommended. Oxygen by inhalation and intravenous administration of fluids supplemented with vitamins given parenterally are usually beneficial. If laryngeal spasm is present, intubation and tracheotomy may be necessary. In case of severe pain, opiates such as morphine, given in small divided doses, will probably be required. Cool showers have been found to be effective in relieving severe itching. Patients suffering from the paradoxical sensory disturbance should be given fluids slightly warm or at room temperature, as well as vitamin B complex supplements. Antihistaminic drugs will be found to be useful in the treatment of scombroid poisoning.

Prevention of Fish Poisoning

Scombroid fishes appear to be particularly susceptible to putrefaction and the development of toxic substances. Geiger has shown that the "histamine" content of the flesh of the Pacific mackerel, *Pneumatophorus diego*, increases from 0.9 mg. per 100 gm. of tissue to about 95 mg. per 100 gm. when kept at room temperature (20° to 25° C.) for about 10 hours (28, 29). In warmer climates scombroids should be promptly refrigerated or eaten soon after capture. Toxic scombroid flesh cannot always be detected by appearance. The toxin

content may be very high with little or no evidence of putrefaction. Scombroid meat having a sharp or peppery taste should be discarded. If the whole fish is available the gills should be examined. Gills should be bright red and without evidence of off-odor. If there is the slightest evidence of putrefaction discard the fish.

If one eliminates scaleless fish from the diet there is no opportunity to come in contact with either tetraodontoids or moray eels, since both are without scales. In Japan, puffer fishes should be purchased from a first-class authorized restaurant having a licensed puffer cook. It is important that the individual preparing the food has a thorough knowledge regarding the fish and its toxicity. One can generally have this assurance by dealing only with the higher class restaurants. It is advisable to eliminate all of the visceral organs and skin from the diet regardless of the species. Although the testes are usually nontoxic, it must be kept in mind that this organ is frequently confused with the violently toxic ovaries, particularly during the season of the year in which the reproductive organs are in the dormant state.

Ordinary cooking does not inactivate the toxin. It may still be present in lethal quantities even when passed through a steam retort in the commercial canning process. The poison can be inactivated chemically by cooking the meat in a strong solution of sodium bicarbonate, ordinary baking soda, for a prolonged period of time. This latter technique also destroys the flavor of the fish and renders it useless for consumption.

Our knowledge regarding the toxicity of most species of tetraodontoid fishes, exclusive of Japanese forms, is exceedingly meager. We do know, however, that many of the tropical tetraodontoid species have produced violent death at one time or another. Unless a species is definitely known to be nontoxic, which is questionable even under the best of circumstances, all tropical forms should be eliminated from the diet.

If it is a question of survival—either eat the puffer or die—and the edibility of the fish is unknown, it is recommended that the fish be eviscerated promptly, and only the musculature be used. Moreover, the meat should be

cut or torn into small bits, and soaked in water for a minimum of 3 or 4 hours. During this period the flesh should be kneaded while in the water, and the water changed at frequent intervals. The toxin is water-soluble and leaching will effectively remove it.

In dealing with potential ciguatera type fishes it should be kept in mind that the most reliable methods of determining edibility involve the preparation of tissue extracts which are injected intraperitoneally into mice, or feeding samples of the viscera and flesh to cats, dogs, and observing the animals for the development of toxic symptoms. Viscera, that is, liver and intestines of tropical marine fish should never be eaten. Also, the roe of most marine fish is potentially dangerous, and in some cases may produce rapid death. Fishes which are unusually large for their species should be discarded, particularly barracuda (*Sphyraena*), jacks (*Craneau*), and grouper (*Epinephelus*), during their reproductive season. If one is living under survival conditions and questionable fish must be eaten, it is advisable to cut the fish into thin fillets and soak them in several changes of water for at least 30 minutes. This will serve to leach out the poison which is readily water-soluble. Do not use the rinse water for cooking purposes. If a questionable species is cooked by boiling, the water should always be discarded. Again it should be pointed out that ordinary cooking procedures do not attenuate ichthyosarcotoxins.

Summary

Fish poisoning is a disease of antiquity. Fishes are believed to become poisonous as a result of their food habits—feeding on marine algae. There is no evidence that plankton or radioactive substances are a factor in the production of the poisons. Poisonous fishes are largely circumtropical in their distribution. Toxin content is greatest in puffers during their reproductive season of the year, but this is probably not true of most other fishes. The distribution of the toxin within the body of the fish is subject to considerable fluctuation, but if the fish is poisonous, some of the poison will be present in the viscera in about 90 percent of the cases. Poisonous fishes cannot be detected by their appearance.

Fish poisoning should not be confused with bacterial food poisoning, with which it has no etiological connections. The overall incidence of fish poisoning is not known. There are eight clinical types of ichthyosarcotoxism recognized at present. With the exceptions of gempylid diarrhea and scombroid poisoning, all other types of ichthyosarcotoxism are characterized by neurotoxic symptoms. The treatment of fish poisoning is symptomatic. Little is known about the chemical and pharmacological properties of fish poisons.

"Model" Law to Cut Poison Deaths

The American Medical Association's Committee on Toxicology has formulated a "model" law for the precautionary labeling of hazardous substances in commercial, household, and industrial chemical products.

The labeling would apply to hazardous substances defined as toxic, irritating, sensitizing, corrosive, flammable, explosive, or radioactive under customary or reasonably anticipated conditions of handling or use.

"Model" text would require declaration of hazardous ingredients and warning statements on the label and in the literature accompanying chemical products.

Requirements of the model law are:

- Labeling of all chemical products containing hazardous substances that are not now regulated.

- Applications of the same labeling standards to chemicals for domestic use and for export. (This will refute the common complaint that inferior standards apply to foreign customers.)

- Prohibition of re-use of food and drug containers bearing their original labels.

- Identification and warnings for strongly sensitizing chemicals which cause allergic or inflammatory reactions in living tissue on contact.

A significant departure in the new law is the deletion of the word "poison." Reference standards, based on animal tests, provide a more consistent and reliable index of poisonous properties than did the former label, according to the committee, not only because there are variations in existing legal limits for poison but also because there is a lack of agreement among scientists on a definition of the term.

Inadequate labeling of potentially harmful chemicals, the committee reports, has been a major handicap to a successful attack on the problem of accidental poisoning. Moreover, lack of information about hazardous ingredients may complicate or delay treatment in emergency situations.

The committee's work in formulating a model law was endorsed by various organizations such as the National Drug Trade Conference, the American Public Health Association, the Cincinnati Academy of Medicine, and the Pennsylvania Pharmaceutical Association.

Heart Disease

Following are two of the papers presented at a session devoted to heart disease during the September 1957 meeting of the American Statistical Association in Atlantic City, N. J.

Methods of Studying the Ecology of Coronary Heart Disease

MORTON ROBINS, M.S.P.H., and
ALFRED M. STEINMAN, M.D.

DURING the past 2 years we have witnessed a tremendous surge of interest in the ecology of coronary heart disease. A conference on the epidemiology of atherosclerosis and hypertension (1), a symposium on measuring the risk of coronary heart disease (2), and numerous papers and articles on this leading cause of death (3-5)—all have served to whet the appetite of both the medical and public health profession for more definitive data. The public is looking for widespread programs for control or prevention, but while our knowledge of coronary heart disease has increased and many leads on etiological factors have been obtained, preventive programs have not yet been recommended. Emphasis is still on the need for additional research into causation.

The development of coronary heart disease is

generally agreed to be the result of complex, unidentified interactions between the human host, with his variable susceptibility, either genetic or acquired, and his total environment.

The study of such interactions is called "human medical ecology" (6) or "scientific epidemiology" (7, 8). Ecology emphasizes the nature of multiple causation and seeks to integrate the diversity of factors involved in disease and to synthesize hypotheses on causation. The ecologic approach has rarely been used in epidemiological investigations of infectious diseases since these studies have been concerned principally with identification of the causative agent—the micro-organism. Interest in medical ecology was revived when epidemiological inquiry was broadened to encompass the non-infectious chronic diseases of unknown etiology. Thus, medical ecology and epidemiology are blood brothers.

The ecologic approach is new, complicated, and expensive. Because of the shortages of trained investigators—at times requiring a team composed of clinician, epidemiologist, biostatistician, and experts from the basic and applied sciences—only a small number of epidemiological studies are currently under way. There is therefore a need to examine our resources and choose our studies with circumspection.

Considering the variation in age-specific incidence rates, the difficulty of accurate diagnosis, and the chronic nature of the disease, which of the alternative methods of data collection is best

Mr. Robins is chief of the Biometrics and Evaluation Division, and Dr. Steinman, chief of the Clinical Studies Division, in the Department of Medicine and Surgery, Veterans Administration.

sued to study causation? An evaluation of the various data collection methods may give some perspective in making a proper choice. A review of ecologic factors may also reveal opportunities for field studies.

Ecologic Factors

Coronary heart disease is ubiquitous, with increasing morbidity and mortality in both young and old. Physicians are able, to some extent, to treat the result of the disease, but they are unable to prevent it. Prevention must hinge upon a better understanding of the basic role that each of the many known, suspected, and as yet unknown factors play in the creation of a thrombus in a coronary artery which has become atherosclerotic.

Factors incriminated as causes of the disease have been identified or evaluated in monographs and texts on coronary heart disease (9,10). An excellent summarization of our current state of knowledge concerning the pathogenesis of the disease is found in a recent paper by Miller and associates (4), and in the report of the Conference on Epidemiology of Atherosclerosis and Hypertension (1). In order to serve as a backdrop for the discussion of study methods, a brief description follows of what we believe to be the factors which require special investigation.

Experimental studies designed to produce atherosclerosis deliberately in animals have led to implications currently being utilized in planning clinical studies in humans, for example, hormone and diet studies. However, the experimental lesions produced in animals are rarely associated with thrombosis, which leads to the suspicion that blood coagulability may be altered.

Another approach to identification of etiological factors is through correlative, fact-finding studies. In essence, most of these studies seek to establish the association of a given physical feature, habit pattern, or result of a physiological or chemical test with the presence of the disease.

The clinician is aware of certain seemingly hereditary factors which appear to be of some importance. Coronary heart disease is observed

more frequently in mesomorphs than in other somatotypes (11). In many instances, the disease is seen in each generation of a given family (12). This suggests the probability that certain basic differences—*anatomical, psychological, metabolic, or mechanical*—exist among members of such families as compared with other groups. This feeling is strengthened by the observation that a synergistic relationship exists between coronary heart disease and certain other diseases with familial concentrations, that is, diabetes, xanthomatosis, hypercholesterolemia, and hypertension (13, 14). These conditions are considered significant when present in males under age 40, and perhaps even more so, in females.

Since some people are nearly entirely free of atheromata while others have dramatic depositions, some basic metabolic defect must be suspected which produces the atheromatous substances. Atherosclerotic plaques may be formed not only in the coronary arteries but in the vessels of the brain, legs, and other body organs and sites. A further question arises from the lack of uniformity in the distribution of atherosclerosis—the presence of plaques at one site bears no necessary relationship to their presence or absence at other principal locations. In addition, in hens, estrogens inhibit the incidence of experimental coronary but not aortic atherosclerosis (15).

Other factors, categorized as environmental influences, also play a role. The effect of climatic changes, ultraviolet light, and smoking have been incriminated. Nutrition probably has an important relationship to the metabolic dysfunction possibly involved in the pathogenesis of the disease. However, specific dietary factors have not as yet been "validated." The relative role of physical activity and the reactions to mental, physical, and biological stress are other significant variables that need further study and quantification.

In regard to the direction of concentrated research in the future, the group of patients under age 40 with an accelerated form of the disease may provide the best source of information ecologically. How do those with manifestations of the disease differ from others in their genetic makeup and habit patterns, including

diet, occupation, mode of living, and associated disease? If significant differences are discovered, are they coexistent or correlated?

The answer to these and many other questions will lead to newer ones. These in turn will lead to the attack upon what we believe is the underlying process: a metabolic defect which produces either atherosclerotic or thrombotic changes, or both, in the coronary arteries, accelerated by such factors as diet, hormonal changes, and habit patterns.

Epidemiological Approaches

Let us now consider the epidemiological approaches in the search for causes of coronary heart disease. We can classify these methodologies into six broad categories: mortality data, hospital statistics, morbidity surveys, morbidity reporting, longitudinal studies, and selected patient cohorts.

Mortality Data

Information on death certificates has traditionally been analyzed to supply clues on statistical associations between demographic characteristics of the population and the incidence of disease. Inferences from analyses of mortality figures have often been substantiated by findings from other epidemiological studies. A large number of statistical studies of coronary heart disease mortality data have been made, and significant differences have been reported for such factors as age, sex, marital status, income, occupation, ethnic group, height, and weight (1). The relationship between dietary fat consumption and coronary heart disease mortality reported by Keys has recently been challenged by Yerushalmy and Hilleboe (16).

It has been suggested that mortality analyses should be pursued because the source data are readily accessible and the study costs are low compared with other epidemiology approaches (1). Moreover, more intensive studies can be designed to increase the epidemiological significance of observed mortality differentials. These mortality studies would start with facts on death certificates and then add information by means of field investigations or by questionnaires to the attending physician and rela-

Guide for Avoiding Arteriosclerosis

A statement advising laymen on how to resist arteriosclerosis, coronary thrombosis, and brain thrombosis has been issued by the National Health Education Committee, Inc., of New York City.

According to the physicians who signed the statement, Dr. Paul D. White, Dr. Howard B. Sprague, Dr. Samuel A. Levine, and Dr. Frederick J. Stare, all of Boston, there are five predisposing factors. They are listed as heredity, overweight, elevated cholesterol level, elevated blood pressure, and excessive cigarette smoking. Hard work in itself, they maintained, cannot be considered a factor.

Persons with a strong hereditary background of arteriosclerosis are particularly cautioned to minimize the effects of the other factors.

The statement lists a number of documents referring to the factors listed. Stressing the importance of arteriosclerosis of the heart and brain, the statement noted that heart and circulatory disease caused the largest number of deaths in the United States. Of the 843,410 deaths in 1956 in this category, most were due to arteriosclerosis.

tives of the decedent. In addition to gathering facts on events leading to death, the studies might provide valuable information on the accuracy of cause of death certification. More profitable coronary heart disease mortality data can also be derived from studies in selected localities where death certification practices are believed to be fairly uniform and accurate.

The major weaknesses of mortality statistics on coronary heart disease as a source of ecologic data are: first, variation in the completeness and accuracy in medical certification of deaths due to the disease; second, questionable correlation between specific mortality rates and incidence of the disease; and third, the impossibility of analyzing from routine tabulations of mortality data many of the ecologic factors believed to be significant in the pathogenesis of the disease.

Accuracy and completeness of cause of death certification depend on the quantity and quality of available physicians' services, and vary with concepts held by physicians concerning the

manifestations of coronary heart disease. These differences in death reporting practices in various subgroups of the population can alter the actual association of coronary heart disease mortality and a particular demographic characteristic (17). Yerushalmy and Hilleboe's study of heart disease mortality statistics for different countries indicates that large numbers of coronary heart disease deaths are reported variably, and are classified as "degenerative heart disease" or as "other diseases of heart" (16).

A basic epidemiological question is whether differential mortality can be used as an index of the relative incidence of initial coronary heart disease attacks among specific population groups, since the disease is chronic and most initial attacks are not fatal. Attacks often recur over a period of many years before the fatal attack occurs. Thus, the age distribution of deaths from the disease may be markedly different from that of patients having an initial attack. Moreover, survivors of an initial attack frequently change their occupation to compensate for their residual disability or from fear of physical exertion. These facts should be recognized in evaluating the epidemiological significance of the mortality differentials of the disease by age, income, occupation, socioeconomic status, and place of residence.

Notwithstanding their limitations, mortality data provide an index of the size and seriousness of the problem. In the absence of specific morbidity and case fatality data, analyses of mortality trends supply indirect evidence of changes in incidence or advances in therapeutic procedures.

Hospital Statistics

The growth of hospital facilities accompanying the expansion of hospitalization insurance coverage and medical care for indigents suggests the increased usefulness of hospital statistics as a measure of coronary heart disease morbidity. Some merit is attached to proposals for a statistical study of coronary heart disease admissions or discharges from a group of hospitals that supply all the inpatient care requirements of a particular area. An example of integrated hospital statistics for a known population is provided by the experience of the

Saskatchewan Hospital Services Plan (18). In the United States, the Commission on Professional and Hospital Activities, Inc. (Ann Arbor), has assembled detailed statistics on patients discharged since January 1, 1953, from hospitals comprising the Southwestern Michigan Hospital Council.

Hospital statistics are considered by some to represent, at worst, a compromise between mortality statistics and complete morbidity data. Extensive hospital morbidity surveys were conducted in New York City in 1933 (19), in Oxford, England, in 1948 (20), and in Ontario, Canada, in 1951 (21). More recently, a large pilot study was conducted in New York City to demonstrate the feasibility of a hospital reporting system as a source of providing useful information on morbidity and for planning medical care programs (22).

While the data on coronary heart disease in tabulations of hospital records suggest differentials in morbidity, their validity has not been ascertained. The question still unanswered is whether the differentials in hospital admission rates are comparable to those based on total incidence of coronary heart disease according to sex, age, race, occupation, and other demographic characteristics. Studies are needed to correlate hospital statistics for a community with estimates of morbidity. In such studies analysis should be made separately for each of the manifestations of coronary heart disease, that is angina pectoris, abnormal electrocardiogram not related to other disease states, and myocardial infarction. Until these questions are answered, indexes of morbidity from hospital admission rates require confirmation by other epidemiological studies.

Detailed clinical, laboratory, and medical history data on hospitalized coronary heart disease patients may also supply leads for other statistical associations related to ecologic factors.

Morbidity Surveys

Morbidity surveys on the health status of a population may take two forms: interviews in sample households, or a complete canvass of physicians and hospitals in a community.

To our knowledge, such a complete survey of physicians and hospitals has not been applied

to the study of coronary heart disease morbidity, but it has been used to obtain morbidity data on cancer. The canvass method is expensive and requires protracted negotiations with medical societies, hospital associations, and health departments. Although the method has been practicable occasionally for cancer morbidity surveys, its results would be highly questionable when applied to coronary heart disease. As contrasted with cancer where pathological laboratory records, hospital records, and mortality reports form a large part of the total morbidity picture, the canvass method applied to coronary heart disease morbidity would rely primarily on reports by cooperating physicians. Retrospective reporting of coronary heart disease is not, therefore, likely to yield a complete picture of its incidence during a prior year.

Morbidity surveys using data from household interviews of a scientifically selected sample of a community, a State, or the Nation have provided epidemiological data on coronary heart disease. An appraisal of heart disease morbidity derived from the National Health Survey of 1935-36 was made by Collins (23) in 1949. More recently, findings have been reported based on morbidity surveys conducted in Hunterdon County, N. J. (24), Baltimore, Md. (25), and the State of California (26). All of these reports generally agree on the uncertain validity of the computed prevalence rates for such chronic diseases as coronary heart disease. Incidence rates derived from data obtained in household surveys are even more tenuous.

Comparisons of coronary heart disease prevalence as measured by household interviews and clinical examinations indicate that the interview data provide minimum estimates. It would also appear that the reported prevalence rates for various subgroups of the surveyed population are subject to varying correction factors of uncertain magnitude.

Despite these limitations, valuable demographic and epidemiological data are byproducts of household morbidity surveys. Estimates are obtained of ecologic characteristics not otherwise available. Such data are useful in assessing concurrent data from morbidity reporting projects, and hospital and mortality studies of the same community. The survey

may also supply rosters of individuals presumably free of coronary heart disease. These randomly selected persons can serve as controls for study patients identified by other study methods.

Morbidity Reporting

Ideally, voluntary reporting by physicians of all new cases of coronary heart disease as they are diagnosed provides the cheapest and most direct approach for acquiring data on incidence. In an appeal in 1930 for voluntary reporting by New York State physicians of certain facts relating to heart disease, Dr. J. V. DePorte, of the New York State Department of Health, said, "In this day, when the immutability of even chemical elements is no longer an axiom, the rigid grouping of diseases into communicable and noncommunicable seems to be altogether artificial. . . . A group of diseases which incapacitate about 300,000 persons in the State is certainly a matter that cannot be excluded from the field of legitimate public health activities by the mere fiat of our individualistic tradition (27)." No action was ever taken on his proposal.

In 1956, Dr. P. D. White called attention to the increased collaboration between the epidemiologist, the cardiologist, and the family doctor as illustrated by their participation in an epidemiological survey of coronary heart disease in the Grand Forks, N. Dak., area (28). During this survey all physicians in the area notified a central committee of each new case of coronary heart disease diagnosed. The reports were supplemented by a household survey giving descriptive data of the population in terms of ethnic background, diet, exercise, habits, stress, smoking habits, and other characteristics. Rosters of the surveyed group are matched against cases of coronary heart disease reported and act as controls in followup studies of both groups. A similarly organized study started in January 1956 in Middlesex County, Conn.

Despite this and other evidence of increased community and physician interest in coronary heart disease, it does not appear likely that voluntary reporting is a practical approach in many localities.

More realistic perhaps is the use of this ap-

proach to determine the incidence of coronary heart disease among more circumscribed groups. Valuable ecologic data can be assembled, for example, on persons covered by comprehensive medical care programs where both physician services and medical records are integrated.

Longitudinal Studies

In prospective or followup studies of coronary heart disease, a cohort of the general population, considered to be free of the disease, is observed over a long period of time to determine the natural history of the disease process. Information is sought on signs or symptoms considered to be precursors to clinical manifestations of the disease. The incidence of conditions can be related to multiple characteristics of the study population which are ascertained by interview, medical examination, or diagnostic tests. Prognosis can be measured in terms of progression of clinical signs and symptoms with reference to the characteristics of each case. In a longitudinal study, provision can also be made after the study has started to introduce a new study variable meriting investigation.

The major limitations of longitudinal studies are: (a) technical difficulties in organizing the study and high costs over the long period required for data collection; (b) attrition of the study group due to noncooperation or movement out of the study area; (c) change of observers throughout the course of the study; and (d) changes in the normal living patterns of the study subjects when they are conscious of the existence of precursors to clinical coronary heart disease.

The first two limitations lead to the question of how to select the study population. Should the study group be a sample of the general population? Or should the study group include all or a sample of a specially constituted group? Obviously, study of the general population permits more valid generalization. However, studies of specially constituted groups, such as industrial employees, Veterans Administration beneficiaries, and participants of pension, disability, or health insurance plans, have the advantages of lower attrition rates and greater cooperation of the study

group. Moreover, study costs are appreciably lower, since medical and laboratory facilities are available and medical records are generally maintained for other medical care purposes.

While selection factors may be present with such variables as age, sex, race, activity status, and income, the observed experience of selected groups can be adjusted by available biometric techniques. In this connection, approximately the same average annual incidence of coronary heart disease, 7 per 1,000, was observed among male civil service employees in the age group 40-54 in Albany, N. Y. (29), and in Los Angeles, Calif. (30), as was found in a sample of the total male residents of Framingham, Mass. (31), in the same age group.

Selected Patient Cohorts

Coronary heart disease patients, or persons having a disease believed to be synergistic in the pathogenesis of heart disease, provide special cohorts for ecologic study. Ideally, these study groups should be scientifically selected from the general universe of patients with the disease. Practical considerations, however, commonly lead to a decision to select hospitalized patients or outpatients as a study unit.

How representative such a group is of the general class of patients from which it is drawn and the methodology of the study plan are concerns of the statistician. The restrictions on the interpretation of findings and the procedures necessary to avoid either erroneous or spurious statistical associations have already been described by Berkson (32), Kraus (33), Lilienfeld (34), and Moore (35). With proper concern for the study design, patient cohorts furnish excellent case material for the study of metabolic defects and specific environmental influences as they relate to the incidence of coronary heart disease.

Retrospective study of coronary heart disease cases generally consists of inquiry into their medical history for suspected antecedent events. Comparison with similar data from a control population provides an indirect method for estimating differential incidence rates. However, when hospitalized patients are used as the study group, the validity of procedures for estimating relative risks (36) is dependent on the degree to which the hospital patients

and the selected controls are representative of these same groups in the general population.

Generally speaking, the longitudinal rather than the indirect approach is recommended for the study of diseases with relatively high incidence. While the total incidence of coronary heart disease is considered to be sufficiently high for longitudinal studies, the incidence among adults under 40 years of age has been found to be so low that the use of the retrospective approach is suggested for this age group. The study of coronary heart disease among these young adults, particularly those without evidence of hypercholesterolemia, hypertension, or diabetes, is of special ecologic interest. This group of patients represents an accelerated form of atherosclerosis.

"Recovered" coronary heart disease patients also serve as cohorts for prospective studies to evaluate the effectiveness of control or prophylactic measures in preventing recurrent attacks. These exploratory studies may provide an understanding of at least one of the components of the causative complex. The advantages of using a cohort of patients instead of a sample of the general population are fairly obvious.

Prospective, longitudinal studies of individuals considered to be particularly susceptible to coronary heart disease, such as diabetics and hypertensives, should also be pursued more intensively than in the past. The size of such cohorts need not be as large as those for longitudinal studies of the general population since the expected differential incidence rates are higher. Moreover, longitudinal studies of these patient groups may possibly suffer from less attrition because of greater interest in their disease. Determination of the environmental factors which trigger symptomatology among these highly susceptible individuals would add significantly to our understanding of the ecology of the disease.

Summary

Public health authorities, who are confronted with the task of reducing the incidence of coronary heart disease, must base their policies and programs on knowledge of the causes. A review of ecologic factors indicates that fu-

ture preventive programs will probably be related to the control of the causes of coronary atheroma and of the environmental influences which accelerate atheromatous depositions and coronary thrombosis.

Epidemiological data are needed to define the differential incidence of the disease among persons with different characteristics and living under different environmental conditions. Such data, when added to pertinent knowledge derived from clinical sources, animal experimentation, and laboratory sciences, will eventually enable the medical ecologist to synthesize a pattern of the multiple causative factors involved.

From this review it is evident that no one all-encompassing field study is likely to settle the epidemiology of coronary heart disease. Significant evidence on causation can be derived from one approach which is not within the capabilities of another. However, because of the short supply of technicians needed for epidemiological research, it is necessary to proceed piecemeal in order to fill the important gaps in our knowledge.

Hypotheses should be intensively investigated by the most rigorous epidemiological method available, despite known limitations in our ability to generalize from the findings. This recommendation does not imply indiscriminate collection of information nor disregard for the principles of validity and reliability.

Three approaches are suggested for future epidemiological studies of coronary heart disease:

1. Routine reporting for a limited time period of initial manifestations of coronary heart disease among adult populations whenever practicable.

2. Longitudinal studies of selected groups whose physical, physiological, and psychological characteristics are determined at the beginning of the observation period.

3. Retrospective and prospective studies of patient populations to determine the relationship between underlying metabolic defects and environmental influences and the incidence of coronary heart disease.

proach to determine the incidence of coronary heart disease among more circumscribed groups. Valuable ecologic data can be assembled, for example, on persons covered by comprehensive medical care programs where both physician services and medical records are integrated.

Longitudinal Studies

In prospective or followup studies of coronary heart disease, a cohort of the general population, considered to be free of the disease, is observed over a long period of time to determine the natural history of the disease process. Information is sought on signs or symptoms considered to be precursors to clinical manifestations of the disease. The incidence of conditions can be related to multiple characteristics of the study population which are ascertained by interview, medical examination, or diagnostic tests. Prognosis can be measured in terms of progression of clinical signs and symptoms with reference to the characteristics of each case. In a longitudinal study, provision can also be made after the study has started to introduce a new study variable meriting investigation.

The major limitations of longitudinal studies are: (a) technical difficulties in organizing the study and high costs over the long period required for data collection; (b) attrition of the study group due to noncooperation or movement out of the study area; (c) change of observers throughout the course of the study; and (d) changes in the normal living patterns of the study subjects when they are conscious of the existence of precursors to clinical coronary heart disease.

The first two limitations lead to the question of how to select the study population. Should the study group be a sample of the general population? Or should the study group include all or a sample of a specially constituted group? Obviously, study of the general population permits more valid generalization. However, studies of specially constituted groups, such as industrial employees, Veterans Administration beneficiaries, and participants of pension, disability, or health insurance plans, have the advantages of lower attrition rates and greater cooperation of the study

group. Moreover, study costs are appreciably lower, since medical and laboratory facilities are available and medical records are generally maintained for other medical care purposes.

While selection factors may be present with such variables as age, sex, race, activity status, and income, the observed experience of selected groups can be adjusted by available biometric techniques. In this connection, approximately the same average annual incidence of coronary heart disease, 7 per 1,000, was observed among male civil service employees in the age group 40-54 in Albany, N. Y. (29), and in Los Angeles, Calif. (30), as was found in a sample of the total male residents of Framingham, Mass. (31), in the same age group.

Selected Patient Cohorts

Coronary heart disease patients, or persons having a disease believed to be synergistic in the pathogenesis of heart disease, provide special cohorts for ecologic study. Ideally, these study groups should be scientifically selected from the general universe of patients with the disease. Practical considerations, however, commonly lead to a decision to select hospitalized patients or outpatients as a study unit.

How representative such a group is of the general class of patients from which it is drawn and the methodology of the study plan are concerns of the statistician. The restrictions on the interpretation of findings and the procedures necessary to avoid either erroneous or spurious statistical associations have already been described by Berkson (32), Kraus (33), Lilienfeld (34), and Moore (35). With proper concern for the study design, patient cohorts furnish excellent case material for the study of metabolic defects and specific environmental influences as they relate to the incidence of coronary heart disease.

Retrospective study of coronary heart disease cases generally consists of inquiry into their medical history for suspected antecedent events. Comparison with similar data from a control population provides an indirect method for estimating differential incidence rates. However, when hospitalized patients are used as the study group, the validity of procedures for estimating relative risks (36) is dependent on the degree to which the hospital patients

Some Observations on the Epidemiology of Heart Disease

TAVIA GORDON

CERTAINLY, the problems in studying heart disease are complex and difficult. To discuss them in detail is obviously impossible here. I will therefore confine myself to a few simple observations.

The first is that the study of heart disease is to a considerable degree still a study of deaths. All too often the first indication we have that a person's coronary artery isn't all it ought to be is when he dies. The final evaluation of an attack of coronary artery disease requires an analysis of changes in the coronary artery and this can be done only by autopsy. There is no equivalent to the biopsy in the study of heart disease.

The second observation is that we must make a distinction between the age group under 65 and the age group over 65 years. When we speak of the alarming increase in heart disease in this country we are referring to the rise in mortality among white men aged 45-64. When we speak of the difficulties of diagnosis we are referring primarily to events after age 65 and

secondarily to events among middle-aged women, which are apt to be equivocal.

The study of heart disease among old people is really for the future. I doubt whether medical science is far enough advanced at present to adequately describe the complexity of chronic illness at advanced ages. Medical pathology is certainly of little help. Usually, the pathologist's report clearly indicates that the person was extensively diseased; the wonder is that he lived as long as he did; but it is difficult to delimit from the multiplicity of defects present any specific, well-defined etiology. Nor is the clinical picture much more help. As has been pointed out, all the organ systems fail at death—the lungs, the liver, the kidneys, and so forth, as well as the heart—but in the absence of a clear-cut etiology the failure of the heart will tend to dominate the picture. If, however, we confine our attention to the study of coronary artery disease among middle-aged men I think we are in a good position to tag our cases and to investigate the epidemiology of the disease.

Unfortunately, vital statistics has gotten itself into a dilemma in the reporting of deaths among older people. If a doctor, faced with a complex and poorly defined pathology, reports a death as due to "old age," the local registrar will in all likelihood request a more definite cause of death. Any student of medical ecology knows what happens next. After a while the doctor starts giving definite answers even when he has only the vaguest notion of the cause of death. And then, of course, the vital statistician becomes understandably skeptical about the reporting of cause of death.

This skepticism about the reporting of cause of death, which is practically an occupational disease of vital statisticians, seems to me grossly exaggerated. I think much of it would evaporate if the skeptics ever attempted to reassign the deaths attributed to heart disease. There are just too many of them. Either they represent a substantial reality or some other diseases represent a public health problem of much greater magnitude than anyone has previously suggested.

It must be granted that the difficulties in the reported death statistics are considerable, but few of them can be resolved by contemplation.

Mr. Gordon is statistician with the National Heart Institute, National Institutes of Health, Public Health Service.

easier. About all you can do that is worth doing is to find out as much about the nonrespondent group as possible. Prospective studies have some advantages in this regard, because there is a reasonable expectation that after a group has been followed for a time the initial bias will tend to diminish, but there is no gainsaying that reliable estimates of the prevalence of cardiovascular conditions in the general population are going to be hard to come by.

Unfortunately, the morbidity survey, which has proved useful in getting prevalence data for many diseases, has not worked out very well for the chronic diseases in general or for heart disease in particular. Contrary to some im-

pressions it is neither cheap nor easy. What is worse it is exceedingly ineffective in identifying persons who would be considered to have heart disease on the basis of a careful clinical examination. No one will dispute that all available epidemiological techniques ought to be considered for the study of heart disease, but there is little advantage in dispersing our substance in a search for shortcuts. This is a real hazard: We are all impatient for answers to our questions about heart disease, and the routine clinical devices for accumulating pertinent epidemiological information are painfully slow and laborious. But here, as elsewhere, the slow and careful way may yet prove the quickest.

Shaw Promoted to Assistant Surgeon General

Dr. James R. Shaw, chief of the Public Health Service's Division of Indian Health, has been promoted to the grade of Assistant Surgeon General.

When the Public Health Service took over the Indian health program from the Department of the Interior in 1955, Dr. Shaw was made chief of the newly created Division of Indian Health. In that capacity, Dr. Shaw is responsible for the administration of medical and public health services for approximately 380,000 American Indians and natives of Alaska.

A career officer of the Public Health Service, Dr. Shaw has been commissioned since 1938. After assignments in Public Health Service hospitals and the U. S. Coast Guard, he became medical officer in charge of the U. S. Marine Hospital, Detroit, in 1949. In 1952 he was named chief of the Service's Division of Hospitals and served in that post until he began his duties in Indian health in 1953 with the Department of the Interior.

In particular, rules of internal consistency for mortality statistics seem to me very slippery. If the mortality sex ratio is high among the white population and low among the Negro population, it may be simply that the death rate for arteriosclerotic heart disease is higher among Negro women than among white. We know that serious arteriosclerotic heart disease is very uncommon among middle-aged women unless they have diabetes or some similar metabolic defect. Conceivably such conditions are more common among Negro women than white. Mortality statistics certainly suggest that. Similarly, mortality sex ratios for arteriosclerotic heart disease are much lower in some countries than they are here. Does that mean those countries are reporting some other disease? Or does it mean that there is a real difference in the balance of factors controlling the appearance of the disease? The suggestion of Edward A. Lew of the Metropolitan Life Insurance Co. that there is a strong environmental component in the sex differentials for arteriosclerotic heart disease seems well taken. I think it is also true that there is an environmental component in the age differentials for this disease.

The question of what factors are involved in the development of coronary artery disease, which is the question that epidemiological studies in this field are concerned with, is a very vexed one. Numerous factors have been implicated, with or without evidence, but none of the really important issues has yet been settled. This is not peculiar to heart disease, however. All diseases may be said to involve a complex interrelation of factors, but the use of a simplified approach still has an obvious utility in the investigation of these factors. It is certainly not necessary that all of the critical factors be recognized or understood for a disease to be controlled, and it is conceivable that one or another of the presently considered factors may provide the key to the control of heart disease. Perhaps diet will prove to be that critical factor. Certainly, there is an increasing weight of evidence suggesting this possibility.

Unfortunately, it has become increasingly difficult to make epidemiological studies of diet in the American population. More and more people are dieting, think they are dieting, or

think they ought to be dieting, and as a result their account of what they eat is apt to be confused and unreliable. In such circumstances the controlled nutrition experiments become more and more critical for our understanding of the role of diet. Currently, such experiments most frequently take the following form: some factor or factors, usually the kind of fat, are manipulated within a more or less carefully controlled regimen, while the remainder of the diet is kept the same or adjusted to maintain a constant caloric intake. The effect of this is measured by some index—total cholesterol or some other serum lipid, usually, since there is some evidence that the serum lipids are associated in a rough way with the risk of overt coronary artery disease.

In this kind of investigation the statistician can be of considerable assistance in designing economical inquiries and rationalizing their results. The usual result of these experiments is that the index goes up and down as the diet is altered, but there are no clear-cut criteria for deciding when the effect of one regimen has given way to the effect of another or (put another way) when we have reached an index level characteristic of a specified regimen. How do you decide when you have reached a steady state and when do you decide that this steady state is not transitory? Furthermore, there are individual differences in response, and while these are no doubt very important they are difficult to evaluate. At the moment this is a very complex but a very promising area of research.

Investigation of other factors in heart disease epidemiology can, at this stage, still be undertaken by field studies. The most serious problem in such studies is the low level of response. You are lucky to get two-thirds of any reasonable sample you select to participate in your study. No one seems to have turned up a way of improving the situation. Going to special groups, instead of to a general population sample, does not seem to help. Captive populations are much less cooperative than might be expected.

The problems of bias arising from nonresponse are certainly serious; and admitting them, unfortunately, does not make them any

ditions of life as an essential part of the United Nations system.

Twin Contrasts

Hours could be spent in elaboration and illustration of any one of these points. I particularly wish to discuss some aspects of the last point—the basic importance of the World Health Organization in raising health levels and creating more stable conditions of life.

Today, we face staggering contrasts. In a few short decades, a minority of mankind, mostly in North America and Western Europe, have almost conquered major communicable disease and have prolonged the span of life so that now the problems and diseases of old age loom large before us. At this very same time, one-seventh of mankind suffer from trachoma, perhaps one-quarter are infested with intestinal parasites; one-tenth still suffer from malaria each year; the dysenteries, often fatal, especially in young children, are too prevalent for calculation.

This type of contrast symbolizes, in the field of health, the vast gap which separates the conditions of life in economically developed countries from those in the rest of the world. The medical science and the technology now exist to conquer these diseases, yet for only a minority of mankind have they been truly conquered. For the first time, peoples in nearly all economically underdeveloped areas are acutely aware that, for some, ill health is not a normal condition of life and, furthermore, that it need not be.

But there is another contrast. On the one hand, there is around the world an insistent demand for health. Consequently, the nations, working cooperatively through the World Health Organization, are beginning to be really successful in the mass applications of the recently developed modern knowledge of the means to health. These applications are ways to the kind of life where human potentialities can be realized; where hunger, disease, and ignorance do not drag man down in his ascent from levels of animal existence. Yet at this very same time, man has made vaulting strides, terrifyingly rapid, in developing the means of mass destruction. These are means which, when

wrongly used, can serve the passions of hate, fear, and the lust to dominate.

These twin contrasts—between conditions of life for a minority of mankind and for a majority and between the technology of human welfare and the technology of destruction—define, in my opinion, the context in which we must now view the importance of the World Health Organization to Americans and to the world. The technical means to health and the organizational means by which nations cooperate to realize health fully form a priceless counterpoise to help balance these contrasts.

Areas of Common Interest

Thirteen years ago, the 73d annual meeting of the American Public Health Association heard an unusual address. Two years before the International Health Conference, it defined forcefully and incisively the basic meaning and value of an organization such as WHO. As so often in the evolution of public health programs, national or international, the Rockefeller Foundation, in the form of this address by its top official, seemed to be lighting a path for others to follow. In speaking on public health as an international problem, Dr. Raymond B. Fosdick, then president of the Foundation, declared:

"The community of nations has got to have a kind of intellectual and spiritual integration before it can be absolutely sure that the forces of violence are under control. Consequently there must be developed for international life new areas and techniques of cooperative action. . . . We need rallying points of unity, centers around which men of differing cultures and faiths can combine, defined fields of need or goals of effort in which by pooling its brains and resources the human race can add to its own well-being. . . ." Dr. Fosdick saw hope only "as we begin to build, brick by brick, in these areas of common interest where cooperation is possible and the results are of benefit to all. . . ."

Public health, he said, can be an important area of common interest, a rallying point of unity. This is my view, and I believe it was the view of the health experts directly responsible for founding the World Health Organiza-

The Importance of WHO to Americans

SURGEON GENERAL LEROY E. BURNET

I AM GRATEFUL to the National Citizens Committee for the World Health Organization for the opportunity to say something today about the importance of the World Health Organization to Americans. My remarks here will be rather in the nature of a personal statement—the impressions and reflections of one who is a relative newcomer to active association with WHO. Of course, my belief that WHO is important existed even before my first attendance at a World Health Assembly, the Eighth, held in the colorful setting of Mexico City in 1955. This conviction was accentuated by attendance in 1957 at the Tenth World Health Assembly in Geneva, the headquarters of the Organization. At this Assembly, I had the privilege of heading the United States delegation. Having to exercise responsibility during the Assembly for the effective and proper presentation of United States views is one of the best ways of necessitating a clear hard look at WHO programs and policies.

I did not find such a look disappointing. The World Health Assembly is genuinely an impressive meeting. The delegates, representing most of the countries of the world, give serious consideration to the world's pressing health needs and how they can be met, resulting in tangible decisions directly affecting the health of millions of human beings such as the decision to drive for eradication of malaria from the world. The Assembly provides unique opportunity to exchange views and to

establish friendly relations with the health leaders of other nations. This is the essence of communication—both more ready interchange of technical information and more international understanding, which basically is understanding between individuals. A further development of the ties between Americans and health leaders in other countries is one among many reasons why I am delighted that the Assembly in May 1958 will be held in the United States.

Any realistic accounting of the benefits which Americans derive from United States membership in, and support for, WHO must include the following:

- Protection against importation of disease through almost universal application of the International Sanitary (quarantine) Regulations.
- Protection of the health of United States citizens traveling abroad through these quarantine measures and through control of diseases at their source.
- Stimulation of markets for United States products and lowering of prices of United States imports through reduction of the enormous drag of disease on economic productivity in many parts of the world.
- Making available to the United States, for application here, the latest health and medical advances in other parts of the world.
- WHO stimulation and correlation of such technical advances and of research.
- Friendship for, and in many cases direct acquaintance with, the United States among health leaders—leaders who are often influential in their own countries outside the field of health.
- WHO leadership in helping countries raise health levels and create more stable con-

This is the keynote address given at the annual meeting of the National Citizens Committee for the World Health Organization, Hotel Cleveland, Cleveland, Ohio, November 13, 1957.

and techniques of cooperation which have proved so rewarding here—techniques of a free society.

These techniques of cooperation, indeed, involve not only WHO and national governments, but extend through them to a multitude of health experts and institutions within countries. The WHO Influenza Study Program is an example of great current interest. In this program, WHO has brought about organized cooperation between laboratories in many countries, which collect, study, and report on influenza virus strains. WHO gives small grants to a World Influenza Center in London and to the International Influenza Center for the Americas, operated by the Public Health Service in Atlanta, Ga., as focal points in this program. In the United States alone, 60 different laboratories cooperate.

Through the program, which also includes the essential participation of a WHO panel of experts around the world, there is constant worldwide watch on the appearance and spread of influenza epidemics and rapid identification of responsible strains. Owing in part to this WHO Influenza Study Program, we in the United States were alerted to the 1957 epidemic and were able to prepare for the invasion of the new strain through production of a protective vaccine.

The world, while now so interdependent, is still a large place. WHO makes use of a decentralized regional structure to an extent unique in international organization. I believe that this decentralization has considerably strengthened WHO as an instrument through which nations cooperate for health. Through the regional offices and regional committees, WHO is brought closer to the needs and governments of member countries, and they closer to WHO. When I recently attended the meeting in Hong Kong of the WHO Regional Committee for the Western Pacific, it was clear that the health leaders of that part of the world and the WHO staff are good friends and work closely together in defining needs and planning programs in health.

Moreover, the decentralized regional structure makes possible more flexibility and experimentation in the WHO programs. An example of a worthwhile experiment is the es-

tablishment of the Institute for Nutrition of Central America and Panama. Under the aegis of the Pan American Sanitary Bureau, the WHO Regional Office for the Americas, and supported largely by the Central American republics, this institute has attained a worldwide influence in nutrition.

Comparison with our own national experience, then, shows that WHO and the nations are evolving a pattern of cooperation along lines to which all Americans can wholeheartedly subscribe. In its sphere, WHO is becoming a "rallying point of unity." With the clearly defined need and goal of health in mind, men and nations of differing cultures and faiths are combining their efforts.

During the past year, some of the Soviet group of countries have resumed active membership in WHO. Even without their participation, WHO has already accomplished a great deal. The eventual character of renewed active membership by these countries remains to be seen. If, in the long haul, it turns out to be a real working together with other nations for health, this would considerably enhance the significance of WHO, as a pattern of cooperative action, applying the technology of human welfare. In such circumstances, the World Health Organization and associated international technical agencies might, given time, contribute more than we realize to bringing the forces of conflict into balance. It is our hope, and our imperative need, that this will be so.

Epilogue

I have given you some of the reflections of a relative newcomer to active concern with WHO affairs. After these reflections had been put on paper, I listened the other night to the President's address to the Nation on science in national security. In concluding his address, Mr. Eisenhower referred to the peaceful uses of science, naming specifically the contributions of science to healing as one of the most important products of the conquest of nature's secrets. Speaking for us all, he said that we will never cease to work for the day when the scientist can give his full attention, not to human destruction, but to human happiness and fulfillment. My theme today has been that

tion. All nations want health, and no nation in the process of gaining health takes it from another—rather, thereby, it helps to advance health everywhere.

This notable address listed activities which a new international health agency might profitably pursue. It is impressive for me, and hopeful, that the list was an accurate preview of WHO's present far-reaching activities: a worldwide epidemic intelligence system; the standardization of biological products; the organized exchange of public health personnel to broaden the technical outlook and stimulate the imagination of health officers; the supplementation of public health activity in countries where it is inadequate; the development of minimum standards of acceptable public health work that can be applied on a worldwide basis; the creation of expert committees and international conferences on special subjects.

These are all activities which, among others, WHO has inherited or initiated, expanded, and made markedly successful in 10 years. They represent the organized cooperative application, worldwide, of the swiftly developing modern technology of health—tangible interrelated action by most countries in the interests of all.

In September 1957, I had the opportunity to see for myself some of the progress in health being made in countries in the Pacific and Asian areas. I found fundamental changes taking place in these countries. Many of them, for example, are establishing spreading networks of rural health centers, which are the basic units of public health protection in that part of the world. During my all-too-short visit to that hospitable country, the Philippines, I saw several such centers. These rural centers, built largely by the efforts of the people in the villages, are so impressive that I confessed to my hosts that they are even better than many of our own here in the United States.

It is evident that in health most of the nations have indeed found an area of common interest. They have begun to build, brick by brick, expanding the techniques of cooperative action. In the context of today's world, this process, associated with international cooperation in other fields, such as education and agriculture, holds out hope. It is lessening, though

slowly, the stark contrast in conditions of life; it is demonstrating incentive and ability to apply science for man's common benefit.

In viewing this essential value of the working of WHO, I have noticed how familiar many of WHO's techniques and modes of operation seem to be. Almost my whole professional life has been spent in the area of domestic inter-governmental health relations within the United States—as a State health official, working in cooperative relationships with Federal agencies, with other States, and with local and voluntary agencies; and as a Public Health Service official, in cooperative relationship primarily with the States, and with the same wide range of other organizations.

Through these effective working relations, we have built in the United States a true community of health effort.

On the plane of international intergovernmental health relations—the relations between WHO and member countries—the same trends are evolving. WHO's interrelationships with member countries seem familiar because, on reflection, they are in many respects quite similar to our relationships in technical matters between Federal and State health agencies. WHO's relationships with other United Nations specialized agencies and international voluntary organizations also remind me of our patterns of cooperation.

Techniques of a Free Society

The member nations of WHO are, of course, independent countries. Even though this is true, the pattern of technical relationships established between WHO and these countries contains the following elements which have a familiar ring to us.

WHO provides expert consultation and assistance to member nations. It develops and demonstrates public health methods which are new, or new to the nations concerned. It stimulates cooperative action among nations on problems requiring such action. And in annual regional and worldwide meetings, the evolving health needs and the future shape of health programs are determined. Through WHO, the nations are succeeding in building on a world scale many of the interrelationships

Arthropod-Borne Encephalitis in 1956

E. RUSSELL ALEXANDER, M.D., and WALTER A. MURRAY, JR., M.D.

DURING 1956, the prevalence of arthropod-borne encephalitis varied considerably in the United States. Eastern equine encephalitis (EEE) returned in a small outbreak of human cases in southeastern Massachusetts, where 12 cases occurred, 8 of them fatal. Although the disease was widespread among horses and pheasants all along the Atlantic and Gulf Coasts from Massachusetts to Louisiana, only 3 other human cases were reported—2 from Maryland and 1 from Delaware. Western equine encephalitis (WEE) affected man and horses in a sporadic and sparse fashion over the western half of the country. St. Louis encephalitis (SLE) was the largest disease problem; there were several small foci in the West, with a large epidemic focus in the high plains of Texas, and an urban epidemic in Louisville, Ky., accounting for the majority of the cases.

The incidence of acute infectious encephalitis in man is reported routinely to the National Office of Vital Statistics, Public Health Service, by all States on a weekly basis. Because of the different criteria used by reporting States, this composite category embraces a crude collection of diseases of central nervous system infections including the arthropod-borne encephalitis group. The 1956 total of 2,624 cases listed according to State serves as a starting point for case appraisal (table 1). This number is the largest annual total reported for the disease category. Final totals have exceeded 2,200 cases only in 1954 and 1955. Marked annual

variation in incidence for the years 1952 and 1956 is seen in figure 1, where sharp peaks in the even years reflect the known larger epidemic occurrence of the arthropod-borne encephalitides (1). Further statistical analysis of the 1956 report data has proved of limited usefulness in appraisal of the arthropod-borne encephalitides.

In 1956, encephalitis in horses produced 1,284 clinical cases, with 493 deaths, as reported to the U. S. Department of Agriculture (2). Cases and deaths listed by State in table 2 reflect reports from widely scattered endemic foci in large geographic areas of the West, as well as highly fatal cases concentrated on the eastern seaboard. Typical of the outbreaks were those in the Columbia River Basin in Washington, western Idaho, and adjoining counties of eastern Oregon. States reporting high mortality were localized in the Atlantic and Gulf Coast sections. That EEE was the cause of the high case fatality rate (80-90 percent) was proved by laboratories reporting isolations of the virus from these areas. In sections of known WEE prevalence, appraisal of reported cases is more difficult; this disease has a much lower mortality rate (15-35 percent), and therefore fewer brain specimens are submitted for laboratory diagnosis.

Eastern Equine Encephalitis

Appraisal of the 15 human cases of EEE reported in 1956 resulted in the classification of 13 as confirmed and 2 as presumptive (table 1). The death of 10 of the patients and incapacitating sequelae in three survivors testify to the severity of this disease. A study of geographic distribution of cases shows a concentration in Massachusetts, where there were 12 cases, the

Dr. Alexander, formerly chief of the Surveillance Section, Epidemiology Branch, Communicable Disease Center, Public Health Service, is now with the department of pediatrics at the University of Chicago. Dr. Murray serves as assistant chief of the Surveillance Section of the Center.

WHO represents this use of science, and that, insofar as it is successful, WHO is building a pattern of common interest and action which can strengthen the conditions of peace.

Those of us who have had opportunity to appreciate all facets of the importance of WHO have a responsibility to meet. The holding of the World Health Assembly in the United States in 1958 gives us added opportunity to meet that responsibility.

If the Eleventh World Health Assembly appears to the American people to be merely another meeting on a technical subject, we shall have missed the boat. If it leads to greater appreciation by our public of the world demand

for health, of the effective moves to fill this demand with leadership by the World Health Organization, we will have partially grasped this priceless opportunity.

It seems to me, however, that taking full advantage of the opportunity means furthering public understanding of the role of WHO in the total world context, the context of sharp contrasts which I have tried to sketch today. The National Citizens Committee for the World Health Organization, as a voluntary association of leaders in health and public affairs, is best equipped to promote vigorously this fuller understanding of why the World Health Organization is actually important to Americans.

United States Host to Eleventh World Health Assembly

The World Health Assembly, the governing body of the World Health Organization, will hold its eleventh session in Minneapolis, Minn., beginning May 28, 1958. This will be the first session of the Assembly to be held in the United States.

Observance of the tenth anniversary of WHO is a special event of this year's meeting, and the Assembly delegates will participate in a commemorative session, May 26 and 27, preceding the regular session.

The World Health Assembly, composed of delegations from WHO's 88 member states, decides the Organization's policies, programs, and budget.

At Minneapolis, the Assembly will consider the annual report of the Director-General on the work of the World Health Organization during 1957. It will approve the program for 1959 and determine the amount of money needed to carry it out. The 1958 budget, mainly contributed by member states, is \$13,500,000.

It will also elect 6 member states, each entitled to designate a person to serve on WHO's Executive Board of 18 health specialists. Six board members retire each year. The Executive Board makes recommendations to the Assembly and gives effect to its decisions.

The Director-General is appointed by the Assembly to serve as the chief technical and administrative officer of WHO, subject to the authority of the Executive Board. Dr. M. G. Candau is the present Director-General and is in charge of a staff of about 1,400 professional workers of 54 nationalities at WHO headquarters in Geneva and in the field.

In a decade of operation, the World Health Organization, working with national health services, has made substantial progress in controlling infectious diseases, training health workers, improving sanitary conditions, and in worldwide health activities of benefit to all countries.

Classification Standards

In order to compare encephalitis activity in the different States from which varying amounts of data were submitted, standards were adopted for the classification of reported cases. These standards are flexible in recognition of the inevitable minor differences in technique between laboratories. The "confirmed" category includes all cases fulfilling the following criteria:

1. Isolation of virus.
2. Fourfold rise in titer of antibodies from acute to convalescent blood specimens.
3. A fourfold fall in titer during the convalescent stage.
4. A single high titer of complement fixing antibodies in a single convalescent serum collected from an area of proved concurrent epidemic.

The "presumptive" case includes all cases demonstrating any of the following:

1. A single high complement fixing antibody titer in an individual with clinical illness compatible with arthropod-borne encephalitis.
2. Case history of clinical encephalitis without any laboratory diagnosis in an area of proved concurrent epidemic.

The only criterion accepted as evidence of current animal infection (horses, pheasants, wild birds, mosquitoes, and other mammals) was isolation of virus.

of them confirmed (table 1). These cases, occurring in 10 States, showed a restricted, early seasonal occurrence, with a peak in mid-August. Analysis of age distribution revealed a concentration in infants (table 3). No fatalities were reported among either confirmed or presumptive cases.

Western equine encephalitis in horses was confirmed by reports of 2 isolations of the virus from brain specimens, 1 in Oklahoma and 1 in Washington. In the California encephalitis surveillance reports diagnoses were confirmed in fourfold, or greater, rises in antibody titer in clinical cases in horses (12). Including serologic and histopathological diagnoses, the U. S. Department of Agriculture lists another 33 instances of confirmation of diagnoses in 10 States (2). It was possible to accept as confirmed cases only those with virus isolation be-

cause of the difficulty encountered in the interpretation of serologic results of single blood specimens submitted without knowledge of the immunity status. The extensive use of vaccines, the difficulty in obtaining adequate history of their use, and the relatively sparse horse populations discourage reliance on reported clinical cases of WEE in horses. Characteristic case fatality of 25 to 35 percent was recorded in the clinical reports of the 1956 epidemics in the Columbia River Basin.

Eight species of wild birds yielded WEE virus in Rhode Island, New Jersey, and Louisiana, as reported by research groups who are working primarily on the ecology of EEE (4-6, 8). For Rhode Island, the isolation of WEE from a chukar partridge is the first demonstration of this virus in the State, but in the other two States there were previous isolations.

The encephalitis surveillance program of the California State Department of Health reported isolations in 1956 of WEE from brains of four grey squirrels.

During 1956, WEE virus was isolated from 307 pools of mosquitoes collected in New Jersey, North Dakota, Texas, Nevada, Colorado, Idaho, Washington, and California, with the most isolations from the last four States. All isolations were from pools of *Culex tarsalis* except 2 in Texas which were from *Culex quinquefasciatus*, and 1 from *C. melanura* in an engorged pool in New Jersey.

Some measure of comparison with previous years is available from reports of the California State Department of Health. Mosquitoes collected in similar fashion from year to year in four county study areas reveal the following:

	1954	1955	1956
Pools tested.....	989	1, 113	1, 047
Pools positive.....	238	82	145
WEE virus.....	151	68	143
SLE virus.....	87	14	2

In terms of WEE virus recovery from mosquitoes, 1956 was not a light year, yet few human cases occurred.

St. Louis Encephalitis

The occurrence of 562 cases of SLE, 227 confirmed, makes this disease paramount among

majority occurring in the southeastern part of the State in an area characterized by numerous fresh-water swamps. In 1938 the same area had 34 human cases of EEE, 25 of them fatal (3). The 1938 and 1956 outbreaks represent the largest and second largest, respectively, both for the State and for the Nation. One of the 1956 cases occurred in Delaware, and 2 in Maryland.

Seven laboratories within 10 Gulf and Atlantic Coast States reported a total of 42 isolations of EEE virus from horse brain specimens, the majority from New Jersey and Massachusetts (table 2). A wide range of seasonal occurrence is represented by isolations from Louisiana in May, and from New Jersey in early November. Although no virus isolations were reported from horses in Alabama and Florida, strong presumptive evidence of EEE is reflected in the reported mortality in excess of 90 percent (table 2).

Followup studies in 1956 on outbreaks of EEE in domestic pheasants resulted in 42 virus isolations from brain specimens submitted from Massachusetts, Rhode Island, Connecticut, and New Jersey.

EEE virus was isolated from 20 serum specimens collected from wild birds during ecologic studies in four States—Massachusetts, Rhode Island, New Jersey, and Louisiana (4-8). A few of the 20 virus isolations were from immature birds, and about equal numbers were from permanent-resident and migrant birds.

Natural isolations of EEE virus were obtained from 11 pools of arthropods collected in three States. From Massachusetts, five pools of unengorged *Culiseta melanura* were positive (7). Two pools of unengorged and one of engorged *C. melanura* collected in New Jersey, and two of engorged *Culex salinarius* collected in that State, yielded virus when tested in the Communicable Disease Center laboratory (9, 10).

These isolations incriminate *C. melanura* as the most probable vector of EEE, since it is the only species thus far to yield multiple isolations of virus from unengorged mosquitoes. This species was in high prevalence in both the Massachusetts and the New Jersey areas. Studies have indicated that their blood meals were primarily from birds and rarely, if ever,

Data Collection

For the past decade, the Communicable Disease Center of the Public Health Service has conducted intensive field studies on the arthropod-borne encephalitides. Beginning in 1955, a systematic effort was made to collect data on the occurrence of these infections throughout the country. Sources included reports from the National Office of Vital Statistics of the Public Health Service, State and local health departments, academic and many other medical and veterinary virus diagnostic laboratories, the Disease Eradication Branch of the Department of Agriculture, and the Walter Reed Army Institute of Research. A report summarizing all the material was then distributed to contributors and others concerned with the control of these diseases.

This nationwide surveillance and continued mutual exchange of data resulted, in 1956, in five concurrent seasonal reports and an annual summary report, which are available on request to those interested in encephalitis research. By defining the pattern of arthropod-borne encephalitis in 1956, it is hoped that the public health importance of these diseases will be further clarified.

The present paper summarizes the information on the occurrence of arthropod-borne infections in 1956 and includes a summary of data for past years.

from man or horses. Therefore, this species may be the prime vector between birds and the occasional vector to humans or horses. It may be, however, that another species less often infected transfers the disease to these mammalian hosts.

Isolations of EEE virus were made from arthropods collected in Georgia, in July 1956 (11). For the first time, the virus was isolated from *Aedes mitchellae* and a pool of mixed species of insects from the genus *Culicoides*, and, for the second time, from *Anopheles crucians*. The separation of engorged specimens from the processed pools was not reported.

Western Equine Encephalitis

The sporadic and endemic occurrence of WEE in the western half of the United States during 1956 resulted in reports of 47 cases, 37

Figure 1. Reported infectious encephalitis cases in the United States, 1952-56.

the arthropod-borne encephalitides in 1956 (table 1). Two large epidemics accounted for the majority of these cases. In the high plains area of the Texas Panhandle, a rural epidemic included over 250 cases of clinical encephalitis. Of these, 89 were confirmed in the laboratory as SLE and 15 as WEE, while the remainder were classified as presumptive. During an urban epidemic in Louisville, Ky., 110 people were affected. Other small epidemic foci were in Colorado, Kansas, Indiana, and southern Kentucky (at the Tennessee border), and sporadic cases were reported from 11 other States. Seven of 31 deaths were confirmed, 2 by virus isolation from brain tissue (table 1). Following the epidemic in Louisville, a 6 percent prevalence of complement fixing antibodies was found in serums from over 700 persons. From this, a crude estimate shows that the ratio of inapparent to apparent infections was more than 200 to 1.

There were 26 isolations of SLE virus from

pools of mosquitoes reported in 1956, still sparse in comparison with reported isolations of WEE. All were made from pools of *C. tarsalis* collected from widely distributed foci in North Dakota, Kansas, Idaho, Colorado, Utah, Washington, and California. Considerable numbers of mosquitoes were collected in Texas and in the Louisville area but no SLE virus was obtained. No SLE virus isolations were reported from wild birds or other animals during that year.

Discussion

A composite of the total virus activity in 1956 for each of the three arthropod-borne encephalitides, as shown in figure 2, represents the sum of all evidence for activity of each specified virus in certain mammals, wild or domestic birds, and mosquitoes.

In some States the only evidence of EEE virus activity in an area was the excess mortality

reducing the reservoir of the virus in nature, is effective in preventing transmission to man. Another point of view holds that the incidence in humans is not directly related to the virus infection rate in mosquitoes, that it has direct relation to the immunity status of the exposed population. Further evidence will be needed to clarify this point.

Although sizable widespread outbreaks of SLE were recorded in 3 States and sporadic cases in 11 others, activity of this virus was not described outside previously known areas (fig. 3). For an analysis of SLE characteristics in different areas, cases were arranged into the following geographic divisions: East Central States (Indiana, Kentucky, and Tennessee), West Central States (Minnesota, Missouri, South Dakota, Kansas, and Texas), and Mountain and Pacific States (Idaho, Colorado, Utah, Nevada, Washington, Oregon, and California).

A study of the sex distribution of cases in these areas reveals markedly equal incidence in males and females in West Central and Mountain-Pacific States (males, 221; females, 220), but a notable predominance of cases in females in the East Central States (males, 49; females, 99). This is a reflection of the data from Louisville, but this same predominance among females was not found in a recent serologic survey.

Marked contrasts occur in age distribution of cases of SLE in these areas (fig. 4). In the

East Central States there is a paucity of cases among children and young people, with peak incidence in the 40- to 70-year age groups. This pattern is typical for 1933 and for the past 2 years. In this area the epidemiological characteristic most likely to suggest SLE is the initial report of seasonal encephalitis in older persons. In sharp contrast, epidemiologists in western States report a typical preponderance of SLE cases in the under-10-year age group, but with a weighting toward the upper level of this age bracket. It also contrasts sharply with the age pattern for WEE and EEE, both of which most frequently affect infants (table 3).

The West Central States have a larger proportion of presumptive SLE cases, as reported from extensive occurrences in Texas and Kansas (fig. 4). In the light of WEE virus activity in these areas, some cases classified as presumptive on clinical grounds in these major SLE epidemic areas actually may have been WEE. This might account for some of the cases in the under-10 age group, and particularly those in infants (table 3). To ascertain the true distribution of SLE, incidence figures should include only confirmed cases. To determine whether the age distribution pattern for SLE in the West Central States adheres to the pattern in the Mountain and Pacific States or to that in the East Central States, or a mixture of the two, requires more exact data.

The seasonal occurrence in these three geo-

in horses, but this evidence, although presumptive in nature, has proved remarkably reliable in the past. In addition, the report data on horses more clearly reflect seasonal occurrence than do data on human cases.

In 1956, the farthest extension southward of human cases of EEE was in Maryland, and the southernmost outbreaks in pheasants occurred in New Jersey. In contrast, during 1955, human cases of EEE were reported from Texas and Louisiana, and pheasant outbreaks from North Carolina and Florida. The seasonal occurrence of human cases was restricted to August and September in 1956; during 1955, onsets in an identical number of reported cases ranged from April to December. The 1956 epidemic in Massachusetts reached a peak during the first week of September, while the four cases reported from Massachusetts in 1955 had onset dates in late September and early October. This may have resulted from a late seasonal increase in mosquito prevalence attributed to the mid-September hurricane Diane. The epidemic peak in 1938 was reached shortly before a mid-September hurricane. Also in contrast with previous years, increased interest and improved laboratory techniques in 1956 have generated an impressive number of EEE virus isolations from wild birds and mosquitoes.

The distribution of WEE virus in 1956 followed expected patterns except for an extension into Rhode Island, as represented by a single isolation from a chukar partridge (fig. 3). For the second year this virus was active in New Jersey, where an impressive number of isolations were made from wild birds and from one pool of mosquitoes (4-6,9,10). These isolations demonstrate the extension of WEE virus activity to eastern shores and give fair warning signals for careful surveillance in these areas for both human and equine cases of this disease.

Again in 1956, as in recent years, an even more restricted interepidemic reporting of human and horse cases occurred, but substantial virus recovery from mosquitoes in several areas indicated that natural reservoirs were maintained and became widely dispersed.

Throughout much of the West, an abundance of the most efficient WEE vector, *C. tarsalis*, and the indications of highly susceptible human populations makes the disease a threat of con-

siderable magnitude. This is especially true in rapidly developing irrigated areas, which may result in the introduction of a greater number of susceptible humans, more wild birds, and new breeding sites for *C. tarsalis*.

The irrigated areas of California contained a considerable number of pools of *C. tarsalis* with WEE virus in 1956. The fact that there were few human cases has been attributed by some to the effectiveness of the mosquito control program in the State, which, although not

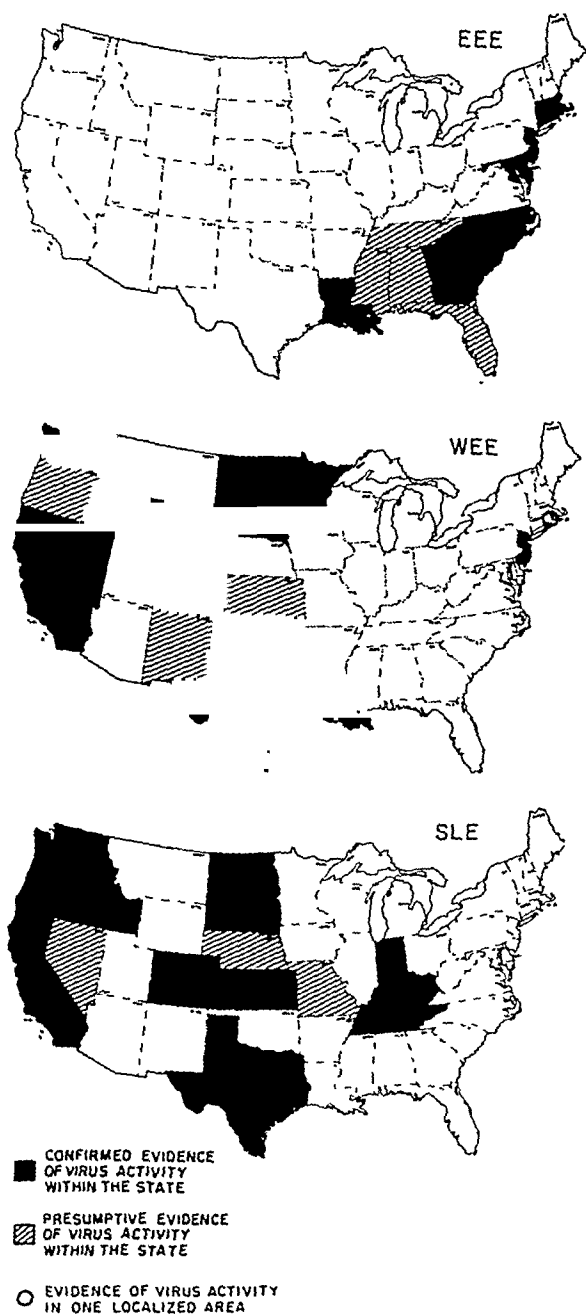

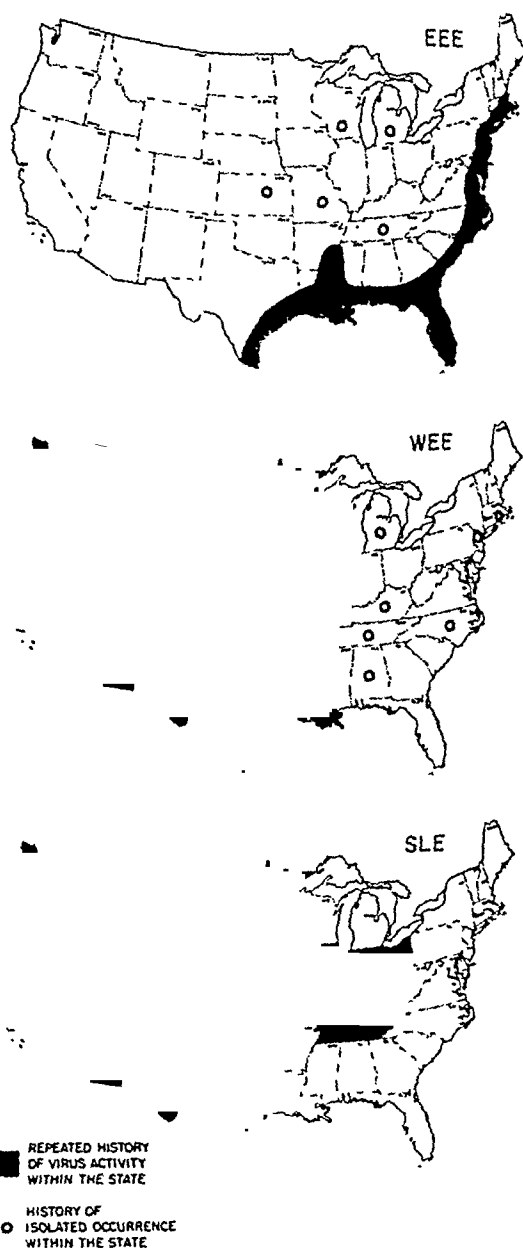

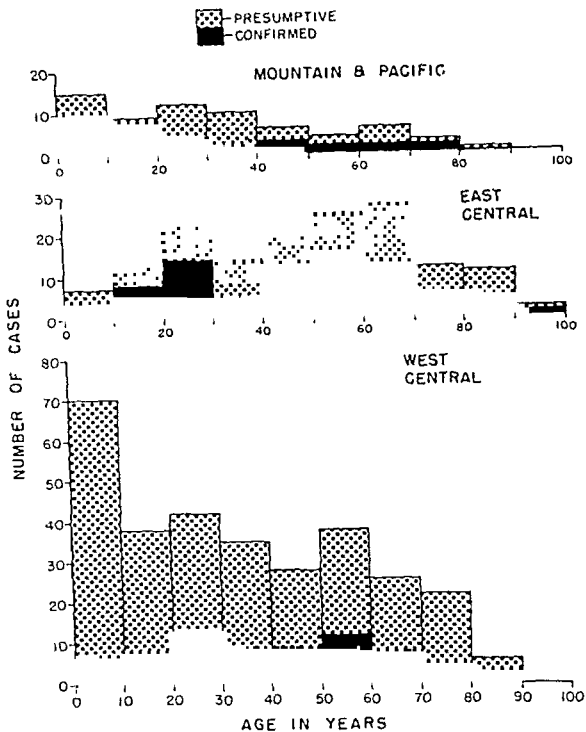

Figure 3. Historical pattern of arthropod-borne encephalitis virus activity, by State, through 1956.

graphic areas reveals a situation similar to that in the age distribution study (fig. 5). Peak occurrence was in August in the Mountain-Pacific States following the August peak of WEE. Also consistent with previous reports was the September peak for SLE in East Cen-

tral States, with abrupt cessation of activity even before killing frosts. In confirmed cases from West Central States, SLE activity is faithfully reflected in the late August peak, but the addition of presumptive cases shifts the curve to a later period. As with the age distribution data, this again is a dilution of the analysis with presumptive cases, which in-

Figure 4. Age distribution of St. Louis encephalitis in 1956, by region.

cluded many with date of report rather than date of onset.

A problem concerned with arthropod-borne encephalitis illnesses is the severity of sequelae after apparent and, possibly, inapparent infections. In certain States, information on sequelae is being obtained as a part of research studies. A longitudinal clinical followup study in California has reported that permanent sequelae are mainly confined to those persons who were in the under-10 group at the time of infection, and that the frequency of severe sequelae appears to be greatest in infants, particularly in infants under 3 months of age (13).

It is interesting to speculate on the possible explanations of the differing epidemiological characteristics in these two areas. Two contributing factors may be operative. First, SLE in Mountain and Pacific States probably is transmitted primarily by *C. tarsalis*, whereas in Eastern Central States the vector is probably *Culex pipiens* or *C. quinquefasciatus*. The characteristics of these species regarding field or house environment may be important, and

Figure 5. Monthly case occurrence of St. Louis encephalitis in 1956, by region.

it is possible that the continued passage of the same virus through species with different incubation periods may lead to minor strain variations. Some laboratory investigations would suggest that such strain differences can be seen in virus isolated in those two geographic areas, although there is no antigenic differentiation.

The second factor to consider is the accumulating knowledge on the immunity of resident populations in the two areas. In certain endemic locations in the West there are significantly higher neutralizing antibody rates to SLE, with little history of clinical disease, than in comparable populations in the East Central States. Although the explanation for the differences in age distribution is not clear, and it is probably more complex than it appears, the fact that there is a significant difference between the two areas is important to record and study.

Studies of the hidden public health problems which may be presented by these diseases are in progress. Increased emphasis on diagnosis of aseptic meningitis may help elucidate cases that are often reported as viral encephalitis.

In many laboratories, work is advancing on the problems of the unidentified viruses, of isolated viruses whose potential for causing disease is unknown, and of disease agents that react with serums of patients from past epidemics of "unidentified encephalitis." Likewise, the problem of encephalitis of unknown etiology might be attacked by better analyses of the diseases reported as encephalitis, particularly the parainfectious encephalitides.

A real problem today resides in arthropod-borne encephalitides that are not now seen in the United States but might be imported. For example, in 1956 an illness in an individual, who became sick on arrival in California from Okinawa, was later diagnosed as Japanese B encephalitis, and in 1955 a case of Venezuelan encephalitis was reported in a laboratory worker in Washington, D. C. The public health hazard in such instances is the possibility of mosquitoes becoming infected, permitting survival and propagation of the virus locally. This, plus the possible introduction of infected mosquitoes, points up the need for increased knowledge and surveillance of arthropod-borne viruses by those responsible for the public health.

Summary

By charting the pattern of arthropod-borne encephalitis during 1956 through surveillance activities, it is hoped the public health importance of these diseases will be further defined.

The increased incidence of the arthropod-borne encephalitides in 1956 was characterized by:

The sporadic occurrence of EEE in horses throughout the Atlantic and Gulf States, with restriction in humans to 12 cases in southeastern Massachusetts, 1 in Delaware, and 2 in Maryland. Substantial virus isolations were recorded from mosquitoes and wild birds in Massachusetts and New Jersey.

Western equine encephalitis occurred diffusely in nature, as reflected by recovery of virus from mosquitoes. Although it failed to spill over into man and horses in epidemic fashion, it still remained a severe disease threat in irrigated areas of the West.

St. Louis encephalitis was the main contributor to the high incidence of reported acute infectious encephalitis. Although the virus was difficult to recover from participants in the natural cycle, the disease was readily apparent in a large rural epidemic in Texas and in three smaller foci in Kansas, Colorado, and Indiana. SLE reappeared in an urban epidemic in Louisville, Ky., for the first time since 1937.

Numerous public health problems, those stemming from encephalitis of unknown etiology, for example, and the possible importation of foreign encephalitides require further study.

WHO Tenth Anniversary Publications

On the occasion of the tenth anniversary of the World Health Organization, the agency has prepared a variety of information materials, described briefly in the following list. Unless otherwise indicated, all items are available at the Office of Public Information, Pan American Sanitary Bureau, Regional Office for the Americas, 1501 New Hampshire Ave., NW., Washington, D. C.

- A series of basic fact sheets on WHO structure and programs, issued in quantity about every 2 weeks.

- A folder entitled "WHO, What it is, What it does." The last page presents in tabloid form, "Ten Years of World Health."

- An illustrated brochure, "Ten Steps Forward." It contains 40 pages of text written by a well-known English science writer and 24 pages of photographs. The publication is sold for 50 cents through the Columbia University Press, International Document Service, 2960 Broadway, New York 27, N. Y. Glossy prints may be obtained from the Pan American Sanitary Bureau.

- A 500-page book in commemoration of the tenth anniversary, covering all phases of WHO. At the end of May 1958 the book will also be available at the Columbia University Press.

- A book on WHO and the public health problem in the Americas and Western Africa. Written by Murray Morgan, a reporter from the State of Washington, it is published by Viking Press under the title "Doctors to the World." Available in May 1958 at regular bookstores.

- *World Health* magazine, formerly the WHO newsletter, special anniversary edition including 80,000 copies in English. The publication will be distributed in May and June 1958.

- A tenth anniversary film, in black and white, running for about 55 minutes, and especially tailored for television showing.

- A tenth anniversary set of 12 photographs entitled "World Health Advances." Each is supplied with an explanatory caption and packed in a large envelope.

- "Pictures of Health," a small booklet using the photographs which appear in the picture set. It is designed for use as a throwaway complementary to the WHO folder.

St. Louis Encephalitis in 1933

observations on epidemiological features

By L. L. LUMSDEN, M.D.

L. L. Lumsden, 1875–1946, a self-styled “shoe-leather” epidemiologist, was a pioneer in indicting the mosquito as a vector of encephalitis. A Public Health Service officer from 1898 to 1939, Lumsden blended rugged realism with an imagination that conceived of the Public Health Service as a logical nucleus for national coordination of State, county, and municipal health activities. He also organized at Yakima, Wash., a full-time county health service, setting a national pattern for local health departments.

THESE OBSERVATIONS on the epidemiology of epidemic encephalitis lethargica are based on findings in the course of studies authorized in a letter dated September 14, 1933, from the Surgeon General of the Public Health Service. The studies included field surveys in St. Louis City, St. Louis County, Independence, Jackson County, Kansas City, Sedalia, Jefferson City, and Columbia in Missouri. East St. Louis, Collinsville, and Chicago in Illinois, and Louisville and Jefferson County in Kentucky.

Intensive studies, including home visits and collection of individual epidemiological case histories, were made in Independence and in Blue Township in Jackson County. In the collection of detailed data in that city and township able assistance was furnished by Dr. W. F. Lunsford, statistician, Missouri State Board of Health, and by the staff of the Jackson County Health Unit. In the other places visited the studies made by the writer were of a general rather than an intensive detailed character. In

the St. Louis region, where next after the Independence region the incidence of the disease in proportion to population was highest and where the large majority of the cases in the epidemic occurred, the intensive detailed studies were made by other officers of the Public Health Service, and their findings, presumably, will be the subject of an exhaustive detailed report.

Chronology and Geographic Distribution

From such evidence as has been obtainable, it appears that the earliest cases of encephalitis lethargica definitely diagnosed in the Missouri epidemic of 1933 had their onset of pronounced symptoms in the last day or two of July and were in a few persons residing in widely separated homes in rural parts of St. Louis County, 10 to 15 miles out from the limits of St. Louis City. Soon thereafter, the disease developed in epidemic rate among the residents of the thickly built-up zone ranging from 1 to 5 miles

In 1933 an unprecedented outbreak of human encephalitis occurred near St. Louis, Mo. When investigations were started by local, State, Federal, and other research workers, it was not known whether a virus, bacterium, or toxic chemical agent was involved. The mode of transmission was equally obscure. During the course of the epidemic, a virus was isolated and characterized—the first time that the etiological agent of any acute epidemic encephalitis of man had been identified. The virus of western equine encephalitis had been under study in the laboratory only since 1930; the virus of eastern equine encephalitis was being studied concurrently with the St. Louis virus and its isolation was also reported in 1933. These were known only as equine diseases. The role of mosquitoes in spreading any of these viruses was not known.

Into this abyss of ignorance and into the midst of a raging epidemic, the Surgeon General of the Public Health Service assigned Medical Director L. L. Lumsden for epidemiological studies. Two conflicting views developed as to the mode of spread of the St. Louis agent. A majority group, influenced by previous epidemiological studies on poliomyelitis and lethargic encephalitis, favored human to human

transmission, while a minority viewpoint, vigorously presented by Lumsden, favored insect transmission.

It is to Lumsden's credit that, after a careful survey of the situation, he reached a sound hypothesis as to the mode of transmission of St. Louis encephalitis, a hypothesis which has proved applicable to other virus encephalitides in North America. This has been abundantly proved by later work. For this reason, Lumsden's unpublished report of 1933, with its sound conclusions as well as its deficiencies, is printed in full at this time.

The ease and frequency with which the viruses of St. Louis, western equine, and eastern equine encephalitis are now isolated from nature and manipulated in the laboratory indicate progress in this field which must be credited largely to a small group of devoted workers who have continued inquiries when there were no epidemics and when there was little interest or support for such research. However, if we were today confronted with another episode of encephalitis lethargica such as the 1933 St. Louis epidemic, it is debatable if its course could be materially altered, the mortality rates suppressed, or the sequelae ameliorated.

—WILLIAM L. JELLISON, *parasitologist, Rocky Mountain Laboratory, Public Health Service, Hamilton, Mont.*

in width in St. Louis County and adjacent to and to the west, north, and south of the city, and also among residents of the outskirts of the city of St. Louis lying next to the affected county zone.

Senior Surgeon J. P. Leake states, "during the early part of the epidemic, the rate of incidence in St. Louis County was 11 times that in St. Louis City." Eventually cases of the disease were reported from every ward of the city, but for the whole period of the epidemic (approximately August 5 to October 14) the rate of incidence was very much higher among residents of the outlying western wards next to the county line than among residents of the "downtown" wards, although the latter include some of the most densely populated areas of the city. According to reports as of October

10, the rate of incidence in the two large wards adjacent to the Mississippi River and farthest downtown from the heavily affected county zone was only about one-fifth of that in some of the outlying wards adjacent to the county zone. For the whole period of the epidemic, the rate of incidence, according to official reports, in St. Louis County was nearly four times that in St. Louis City.

If the rates of incidence of encephalitis in the different areas of St. Louis City were, as appears probable, even roughly or generally in inverse proportion to the distance from the St. Louis County zone of high prevalence, such occurrence taken alone would appear to be of some epidemiological significance, and, perhaps, would become of more epidemiological significance if considered in connection with

in width in St. Louis County and adjacent to and to the west, north, and south of the city, and also among residents of the outskirts of the city of St. Louis lying next to the affected county zone.

Senior Surgeon J. P. Leake states, "during the early part of the epidemic, the rate of incidence in St. Louis County was 11 times that in St. Louis City." Eventually cases of the disease were reported from every ward of the city, but for the whole period of the epidemic (approximately August 5 to October 14) the rate of incidence was very much higher among residents of the outlying western wards next to the county line than among residents of the "downtown" wards, although the latter include some of the most densely populated areas of the city. According to reports as of October

10, the rate of incidence in the two large wards adjacent to the Mississippi River and farthest downtown from the heavily affected county zone was only about one-fifth of that in some of the outlying wards adjacent to the county zone. For the whole period of the epidemic, the rate of incidence, according to official reports, in St. Louis County was nearly four times that in St. Louis City.

If the rates of incidence of encephalitis in the different areas of St. Louis City were, as appears probable, even roughly or generally in inverse proportion to the distance from the St. Louis County zone of high prevalence, such occurrence taken alone would appear to be of some epidemiological significance, and, perhaps, would become of more epidemiological significance if considered in connection with

the direction of prevailing winds, with main currents of travel by persons, and with other possible factors in the spread of disease.

According to records of the State board of health, the reports of cases of encephalitis lethargica, by weeks, in the cities and counties of Missouri in the period August 1 to October 21, 1933, were as indicated in table 1 (1).

From these records it appears that the epidemic began and also reached its height in the St. Louis region about a week or two before it did in the Independence (Jackson County) region, but that the marked decline in the epidemic occurred somewhat sooner in the Independence region than it did in the St. Louis region. It is interesting to note that of the two

regions of the State which were most heavily affected, one (St. Louis) is on the east border of the State and the other (Independence) is near the west border about 300 miles from St. Louis and that, with the exception of Columbia in Boone County, there were very few cases reported in the cities and the 7 counties along the main lines of travel between St. Louis County and Jackson County. In the three counties adjacent to St. Louis County, with a total population of 82,436, only 8 cases were reported—4 in St. Charles, 1 in Franklin, and 3 in Jefferson—and in none of the 7 counties along the main line of travel between St. Louis and Jackson County was a case reported.

Within the period August 1 to October 21, not a case was reported in either Jefferson City, with a population of 21,596, or in Sedalia, with a population of 20,806. Both of these cities are on the main current of travel between St. Louis and Kansas City. The State Fair, which was attended by many persons from the St. Louis and Independence regions, was held at Sedalia August 12 to 19, inclusive, when the period of causation of the disease in the St. Louis region was, presumably, at its height. Columbia and Independence, which cities are somewhat offside from the main current of travel between St. Louis and Kansas City, were stricken—the former moderately and the latter very severely. The incidence in Independence and in the zone about 6 miles wide (in Blue Township, Jackson County) between that city and Kansas City was much higher than the rate in St. Louis City and County. As nearly as the population can be estimated, the incidence in the area (of Blue Township) lying between Independence and the northeast section of Kansas City was 1 case to about 125 of population. In Jackson County outside Independence, Blue Township, and Kansas City, not a case was reported.

In Kansas City, with a population of 399,746, only 16 cases were reported to the State board of health between August 1 and October 21. The records of the Kansas City Health Department, however, showed on September 28 that 33 cases developing in the city had been reported to that department since August 1. It is exceedingly doubtful that as many as 100 cases actually occurred among residents of Kansas

City during the epidemic. At even such liberal estimate the case incidence in that city would have been only 1 to about 4,000 of population. It appears that a large proportion of the cases developing in Kansas City were in persons residing in the northeastern section of the city near the Jackson County (Blue Township) line.

In East St. Louis, Ill., with a population of 74,347, directly across the river from St. Louis, Mo., and connected therewith by bridges over which there is a constant current of traffic, only 3 local cases were reported between August 1 and September 25, but in Collinsville, Ill., a scattering village of 9,235 population located about 6 miles east of the city limits of East St. Louis, 4 local cases were reported within that period.

In Chicago, Ill., with a population of about 3,500,000, only 3 cases of encephalitis lethargica among residents were reported between August 1 and September 29. The number of cases reported in 1932 was 21 and the number reported in the period January 1 to August 1, 1933, was 6. In view of the tremendous amount of traffic between Chicago and St. Louis and Kansas City, the fact that Chicago was not reached by the epidemic is significant.

If encephalitis lethargica has an incubation period of 1 or 2 weeks, or more, as is assumed—apparently without definite reasons—by some observers, it is remarkable that a considerable number of persons while incubating the “infection” did not go from the epidemic areas to Chicago and have the onset of the disease while there. If the disease is caused by an infection which is transmitted either through personal contact or by flying insects, such as mosquitoes, which will travel by train, Chicago’s complete escape from the epidemic would be difficult to understand, unless the incubation period (if any) of the disease is very short and the “infection,” if conveyed by insects, is harbored by the “carrier-insects” for only a short period—less than 12 or 24 hours.

In Louisville, Ky., with a population of 307,745, located about the same distance by automobile or train travel from St. Louis as is Chicago, 28 cases of, with 9 deaths from, encephalitis lethargica were reported among residents of the city between August 1 and Septem-

ber 21, 1933. In addition to these, about 20 suspected cases were reported. Judging by the records of the city health department and the findings in the survey of the situation, the probability is that approximately 60 cases of the disease developed among the residents of Louisville in the period August 10 to October 10. A large majority of the cases were among persons residing in one or the other of two outskirts of the city about 6 miles apart.

Why was there such a distribution of the disease in the epidemic? Why did the incidence become less as the densest centers of population farthest away from the affected suburban zones were approached in St. Louis City and Kansas City and Louisville? Why did not the disease follow the main currents of human travel? Why did Jefferson City, Sedalia, and Chicago entirely escape? Why did Columbia have a fairly high prevalence? Why did Collinsville have a rate of incidence of the disease 10 times that of East St. Louis? Why were the cases in Louisville mainly in persons residing in one or the other of two outlying sections of the city about 6 miles apart? The answers to these questions should lead to sound epidemiological conclusions as to the mode of spread of the disease.

Judging by the reports recently received, it appears that with the advent of cool or cold weather in each of the heavily affected areas, the disease promptly ceased to prevail in epidemic proportions—in the Independence region somewhat before it did in the St. Louis region, although the epidemic began in the former region 2 weeks or more later than it did in the latter. The decline or the practical termination of the epidemic with the advent of cool or cold weather may be, of course, entirely coincidental and present no relationship of cause and effect: but to our elder epidemiologists it is somewhat remindful of the observations on yellow fever incidence in the days prior to 1900 when that disease, too, was a "mysterious malady."

General Considerations

The high rate of incidence of encephalitis lethargica in persons in the older age groups, the rapid spread of the disease over large areas in the regions affected, and all of the other gen-

eral epidemiological features suggest that in this epidemic in Missouri we were dealing with a new or a comparatively new disease or a new type of an old disease. At the beginning of these studies the nature of the causative agent of the disease was entirely unknown.

So far as the writer was informed, it has not been definitely determined whether the causative agent is a microscopically visible organism, a filtrable virus, or a toxin. Therefore, it seems right throughout the course of the studies to try to keep entirely open-minded, to be not overly influenced by superficial appearance of analogy with any other disease, to consider constantly the possibility that in this epidemic of encephalitis we were dealing with a disease or a type of disease different from any other which previously had prevailed in this country or, perhaps, in any other country, to collect facts carefully and thoroughly, and to consider every possible factor which might operate in the causation and spread of this disease.

The geographic distribution of the epidemic appeared to furnish a lead. There must have been some definite difference between the communities which were heavily affected and those which were lightly affected or not affected at all. The determination of these differences and whether they were consistent seemed highly important. In the areas heavily affected, the disease appeared to attack in about the same proportion rich and poor, white and Negro, and persons of different national descents. Difference in sources of water supplies for drinking and culinary purposes in two or more adjacent areas did not appear to affect the prevalence of the disease. Difference in food habits did not appear to affect prevalence. No evidence was found of a disproportionately high prevalence of the disease among users of milk, ice cream, or any other food from any one source. Therefore, it seems that if either water supplies or food supplies had operated in the spread of the disease all of the supplies in the large areas affected would have to have been about equally involved.

The first 2 days of these studies (September 18 and 19) were spent by the writer in the St. Louis region for conference and observation with other officers engaged in intensive studies in that region. We made repeated trips back

and forth over the St. Louis City line through different parts of the then heavily affected, thickly built-up suburban zone in St. Louis County.

As the city line was crossed going into the suburban zone, one difference was striking and very apparent. In the city area there were both sewage and sewerage. In the suburban area there was sewage but no adequate sewerage. In the city the sewage is carried away by trunk sewers to the disposal plants and eventually to the river. In the suburban zone, which is a section of hills and dales, there is no general sewerage system and the sewage from the small municipalities and from the thousands of dwellings and places of business is carried by small municipal sewers or by private or individual sewers direct from toilets or from cesspools or septic tanks to nearby creeks or streams. These heavily polluted open streams are very offensive to sight and smell. Even if they had nothing to do with the causation or spread of any disease, they are bad. They should not be tolerated in any community.

Since the rainfall in this region in the summer of 1933 was less than that for any of many previous summers, sewage was concentrated to an unusual degree in these creeks in the summer and early fall of this year. Mosquitoes, mainly (or almost solely) *Culex pipiens*, were breeding in myriads in these heavily sewage-polluted creeks. The citizens generally in these areas stated that mosquitoes were much more numerous and much more of a pest this season than they had been for many years before. Surgeon L. L. Williams, Jr., stated that *C. pipiens* and *Culex quinquefasciatus* mosquitoes bred under such conditions are capable of and addicted to long flights—2 miles or more. Anyhow, in September of this year, *C. pipiens* mosquitoes were observed from time to time in rooms in some of the farthest downtown leading hotels of St. Louis. The probability is that they were present more or less in all parts of the city, but most abundant in the outlying western areas.

Mosquito breeding in open sewage-polluted creeks was kept in mind in the course of the observations in other communities. East St. Louis is located in a flat, river bottom area instead of in one of hills and dales, and there

was comparatively little, if any, mosquito breeding in exposed heavily sewage-polluted streams or other waters. Collinsville, Ill., however, is located in an area of hills and dales—very similar to that of the St. Louis County zone—and there was observed on each of the two sides of the village a heavily sewage-polluted creek in which in September mosquitoes (*C. quinquefasciatus*, mainly) were breeding in myriads. In the Independence and Blue Township region between Independence and Kansas City creeks were heavily sewage-polluted and *C. pipiens* were breeding therein to a much greater degree apparently than in the St. Louis County region as a whole. Columbia, Mo., presented this condition to a considerable degree. Kansas City, Jefferson City, Sedalia, and Chicago appeared free from it. Louisville, Ky., presented it to a marked degree in the immediate vicinity of each of the two areas in which encephalitis was highly prevalent.

Thus, throughout the limited observations made by the writer, the abundance of sewage-bred mosquitoes (*C. pipiens* or *C. quinquefasciatus*) appeared to be the only consistent factor of difference between communities which were heavily affected by encephalitis in this epidemic and those which were not affected or only slightly affected.

This one fact is not conclusive but it is suggestive and, therefore, seems worthy of careful consideration and further study. It is possible, of course, that some other insect, such as the sandfly or buffalo gnat (Simuliidae), or some unusual large fly or one not yet even thought of is the vector; but the evidence obtained in the course of these studies points to the mosquito as the most likely conveyor—if the disease is conveyed by insects. Every fact observed in the places visited by the writer seems in line with the hypothesis of mosquito conveyance and not one fact observed is in conflict with it. Thus, hypothesis passes into theory.

The geographic distribution and most other general features of the epidemic appear definitely out of line with the other much discussed hypothesis—and the one yet favored by some of the observers—that the disease is caused by an infection discharged in the secretions from the upper respiratory passages of patients and “carriers” and is transmitted

from person to person through direct and indirect personal contact. In the outbreak of malignant smallpox in Kansas City and vicinity in 1921 and in the influenza epidemic of 1918, the epidemiological pictures were very different from that of this encephalitis epidemic.

In view of the fact that only one person in about a thousand in the St. Louis region developed encephalitis in the course of the epidemic, negative results from human experimentation evidently would have to be produced on a large scale—involving hundreds of persons—to tend to nullify the mosquito conveyance hypothesis or any other reasonable hypothesis.

In considering the hypothesis that encephalitis is caused by a micro-organism, a virus, or a toxin conveyed to susceptible persons by mosquitoes, a number of interesting questions arise, such as the following:

1. Do the mosquitoes before becoming capable of conveying the causative agent have to feed on the blood of a person ill with the disease, or of one harboring the causative agent without being ill, and carry the agent through a developmental cycle as is the case with yellow fever and malaria?

2. May adult mosquitoes become capable of conveying the causative agent mechanically—as appears to be the case with some of the insects which convey the infections of some of the trypanosomiasis—after feeding on the blood or some of the secretions or excretions of a person (ill with the disease or before, after, or without illness) harboring the causative agent?

3. May mosquitoes while in the larval stage acquire the causative agent in their feeding on matter polluted with human excretions or secretions or on other matter and continue to harbor the agent and be capable after reaching adult life of conveying the agent to persons by biting or otherwise?

4. If mosquitoes become loaded with the agent before leaving their breeding places (as appears to be the case with the mites which convey the infection of tsutsugamushi fever) is it one out of many—thousands or millions—or a considerable proportion of them which becomes loaded?

5. Is the causative agent harbored by the

loaded mosquitoes for a period of days or weeks or for only a few hours after leaving their breeding places?

6. Is one loaded mosquito capable of conveying the causative agent to a susceptible person by one bite or are a number of bites by one or many loaded mosquitoes required?

7. Do other animals—such as poultry, birds, cows, horses, squirrels, rodents, or even fish or reptiles (dead or alive)—serve as sources of the causative agent from which mosquitoes may transmit the agent to man?

8. Are persons who “do not mind” mosquitoes, and who sit out in the open after dusk of evening and “take them,” more likely to contract encephalitis than are persons who are “poisoned” by mosquitoes and who try to get away from them?

9. Is it possible that the part of the body bitten is a determining factor, as is the case with rabies virus, tending to explain why elderly persons with well-clad bodies and whose faces and necks present the main field of attack for mosquitoes are more likely under comparable conditions of exposure to loaded mosquitoes to have the causative agent conveyed effectively to them than are lightly clad young persons whose legs and arms present the main area of attack?

10. Are persons with foul mouths and offensive breaths or with otitis more likely while sleeping under cover at night to attract *C. pipiens* mosquitoes to their heads and necks than are persons with clean mouths sleeping in the same rooms or houses?

Most of these questions, presumably, will have to be answered, if at all, by the findings from future studies; but if in the meanwhile the spread of encephalitis is not proved to be due to some agent or agency other than mosquitoes, these questions are and will be serious practical ones.

The sudden spread of the disease over large areas, the very unusual occurrence of more than one case in one family, and the other general features of the epidemic seem to suggest that if the causative agent is conveyed by mosquitoes, it is conveyed by filth-breeding and filth-loving mosquitoes (*C. pipiens*) which, in rare exception or in considerable proportion, come “loaded” from some of their breeding places and are capable for a short time of conveying

the causative agent without previously having fed on the blood of a person or other living animal.

Incidence in Institutions

Institutions, of which there are quite a number in the outskirts and suburbs of St. Louis City, seemed to furnish especially strategic situations for studies of encephalitis. Four institutions were visited. The first one, an institution for mental cases administered by Sisters of Charity, had a population, including personnel and inmates, of about 400. It is located on a hill about 2 miles from Clayton in St. Louis County and in a zone in which encephalitis was highly prevalent. All parts of the building were found to be well screened and otherwise in excellent hygienic condition. Not a case of encephalitis developed at that institution during the epidemic.

On a hill in one of the outskirts of the city in the vicinity of a section of the St. Louis County zone which was quite heavily affected are three city institutions, the Hospital for the Insane, the Isolation Hospital, and the Infirmary (Almshouse). They face north on the same street and are in adjacent grounds. The Isolation Hospital is in the middle. The prevailing winds are from the south. All three are supplied with milk, meat, vegetables, and other foods purchased by the city from the same contractors. All three obtain their water supplies from the same source, the city public supply.

At the time of the survey, on September 25, the Isolation Hospital and the Hospital for the Insane were found to be well screened and otherwise in excellent structural condition, but the Infirmary was found to be poorly screened and in some parts in need of structural repair. Doctors, nurses, and other persons in each of these institutions were queried regarding mosquitoes in wards and other sleeping quarters at night. The report for the Isolation Hospital and the Hospital for the Insane was that very rarely was a mosquito noticed in the sleeping quarters, but the report for the Infirmary was that mosquitoes were abundant and very troublesome in the sleeping quarters. At the Isolation Hospital, in which over 300 cases of

encephalitis had been treated during the epidemic, not a case had occurred among the personnel. At the Hospital for the Insane with a population, including personnel and inmates, of about 4,000, not a case had occurred.

At the Infirmary, with a population, including personnel and inmates, of about 1,200, 13 cases of encephalitis had developed during the epidemic. Two of these were in female attendants who were domiciled with six other female attendants in a large ward on the second floor of the south side of the building. The first case was in an attendant who slept in a bed directly in front of the door leading from an open porch into the ward. The screen on this door had sagged and furnished little protection against mosquito invasion. The second case, developing 6 or 7 days after the first, was in an attendant whose bed was at the same end of the ward and located a few feet toward the wall from that of the attendant who developed the first case. The other six attendants who were domiciled in this ward and who were not stricken with the disease slept in beds located at the other end of the ward in the part of the quarters farthest away from the door. The space of about 40 feet between the set of 2 beds and the set of 6 beds was used as a lounge.

At both the Hospital for the Insane and the Infirmary, contact through visitors and otherwise with the outside world was free during the epidemic; but, for obvious reasons, there was more restriction at the Hospital for the Insane than at the Infirmary with respect to permitting inmates to visit homes in the community and go out into and sit around in the institutional grounds after sundown.

Intensive Studies in the Independence Region

The encephalitis studies in the region of Independence were begun on September 19 and were terminated on September 28. They comprised (a) a survey of sanitary and other general conditions in the community, (b) examination of the morbidity and mortality records of the health office of Independence City and of the Jackson County Health Department, (c) a search for mosquito breeding places in the vicinity, (d) visits to homes and collection of detailed epidemiological histories

of 19 cases of encephalitis among residents of Independence City and of 28 cases among residents of Blue Township in Jackson County.

Independence is the seat of government of Jackson County. It is an attractive little city with rolling topography, wide, clean streets and well-kept homes, and without serious overcrowding in any part. Economic conditions generally appear considerably above average for cities of its size. The land area is about 3 square miles and the population in 1930 was 15,296, 14,450 whites and 846 Negroes (U. S. Census). Of the whites, only 488 are foreign-born.

Independence is located east of the northeast section of Kansas City, the distance by road between the limits of the two cities being about 6 miles. The public water supply, furnishing over 90 percent of water used for drinking and culinary purposes in the city, is obtained from the Kansas City supply. The milk supplies and other dairy products distributed in the city are from Kansas City and from local dairies and nearby dairy farms. About 50 percent is said to be pasteurized and most of the remainder to be grade A raw. Practically all meats sold in the city are distributed by Kansas City dealers. Vegetables are mainly from Kansas City markets and nearby farms.

About 80 percent of the private dwellings and public places are connected with the city sewers and the remainder are provided with septic tanks, cesspools, or privies. The main trunk sewer, carrying about two-thirds of the city's sewage, discharges into Rock Creek, a shallow stream ranging in width from 3 to 10 feet, meandering in and out along the southern outskirts of the city, and finally discharging into a lake in Mount Washington Cemetery about 1 mile from the eastern limit of Kansas City. The sewage before discharge into the creek (in the south central outskirts of the city) goes through some sort of sedimentation treatment which evidently is inadequate because the sewage was found highly putrescible after it entered the creek. Samples of water dipped from Rock Creek and from other heavily sewage-polluted creeks in the other outskirts or suburbs of the city were found, on September 22, to be literally teeming with mosquito larvae, which on examination proved to be *C. pipiens*.

The locally prevailing winds are from the south.

Local Prevalence of Encephalitis

Independence was severely affected by the encephalitis epidemic. From August 19 to October 21, 1933, 63 cases with 14 deaths were reported among the residents of the city. Sixty cases were in white persons and 3 were in Negroes. The case incidence for the whole period of the epidemic in Independence was 1 to about 250 of population.

Blue Township in Jackson County, especially that part lying between Independence and Kansas City, was also severely affected. In that intercity zone the case incidence was 1 to about 125 of population. The population of Jackson County, exclusive of Independence and Kansas City is 55,406. Of them, 27,356 reside in Blue Township outside Independence. In this total rural population of Blue Township there were reported from August 19 to October 14, 1933, 61 cases of encephalitis with 8 deaths, a case incidence of 1 to about 450 of population.

In the total population of 28,056 in the other rural townships of Jackson County not a case was reported within that period. All cases

reported in Blue Township outside Independence were in white persons. In the rural part of the township, only 60 Negroes reside. The area of Blue Township west of Independence, which probably was more heavily stricken by the epidemic than any other area of considerable population, is hilly. In the dales between the hills are numerous creeks. Most of these creeks are polluted with sewage and are heavily polluted in periods of drought such as that of the summer of 1933. Samples of water dipped from a number of places in those creeks on September 22 were found to contain myriads of *C. pipiens* larvae. The report from the residents generally was that mosquitoes were much more abundant in July, August, and September of this year than in the corresponding months of any previous year within their recollection. The opportunity for the breeding of mosquitoes in heavily sewage-polluted water in this region, in proportion to population, seemed several times as great as that furnished in the St. Louis County region.

The zone between Independence and Kansas City is quite thickly built up, resembling for the most part a scattering village. The majority of the residents appear to be in good or fair economic circumstances. Most of the water used for drinking and culinary purposes in this zone is piped from the Kansas City supply. The large majority of the homes seem well constructed and well kept. It was surprising to

find among the streets at the front of some of the rows of those attractive homes gutters filled with and flowing with highly offensive sewage.

Dates of Onset of Cases

In a large majority of the cases especially investigated, the onset of definite illness was sudden or after a prodromal period of only a day or two. The dates of onset (usually those upon which the patient took to bed) of 51 cases in Independence and of 59 cases in Blue Township (outside Independence), whose histories on this point were obtained, were evenly distributed throughout August and September. [Tabulation omitted.—EDITOR.]

Age and Sex

The occurrence of cases of encephalitis among 111 persons in different age-sex groups is shown in table 2. It is interesting to note that in persons under 15 years of age the case incidence was much higher among males than among females.

The case incidence among persons in different age groups among 15,296 residents of Independence is shown in table 3.

Table 4 presents the number of persons in the different age groups in the rural farm and the rural nonfarm population of Jackson County, the number of cases of encephalitis in each of

the age groups, and, since the large majority of the cases were in the nonfarm residents, the case incidence based on the nonfarm groups of the population.

Findings at Affected Homes

In the course of epidemiological studies, the ascertainment of definite information as to the possibly salient conditions to which the persons affected with encephalitis have been exposed prior to illness is of primary and fundamental importance. Therefore, visits to the homes of persons in which cases of encephalitis had developed in the Independence region were begun with interest and with an effort toward complete openmindedness.

Of the affected homes, 18 in the city and 27 in the township (outside Independence) were visited. At the second home visited, a history was obtained that within the 3 weeks prior to the onset of the patient's illness, 25 of about 100 chickens kept in the yard had died of some sort of convulsive disease. At the fourth and fifth homes, a history was obtained that within several weeks prior to the development of each case, goldfish kept in a bowl in the house or in a rock garden in the yard had been dying. At the seventh home visited, the wife had captured three strange insects in the bedroom of her husband the day he became ill with encephalitis. These insects, resembling somewhat the drones of honey bees, were later identified at the St. Louis headquarters of the studies as moths of unusual occurrence in that part of the world. The convulsive chickens, the sick goldfish, and the strange moth tales, however, did not continue, no history of any of them being obtained at any of the other stricken homes visited.

Especial consideration was given to the possibility of the encephalitis epidemic having been caused by a toxin—comparable to that of botulism—conveyed in some widely distributed canned or otherwise prepared food, but the histories of the cases definitely eliminated such etiological possibility. Attention also was given to the possibility of unhealed wounds, sores, bad tonsils, and diseased gums serving as a nidus of infection. The proportion of cases among persons with diseased gums was found to be quite interesting.

Possible Susceptibility Factors. No evidence was obtained to suggest that hay fever, asthma, hives, herpes, previous attack of any infectious disease, vaccination against smallpox, or immunization against diphtheria or typhoid fever tended to make one especially susceptible to the disease.

Of the 47 cases of encephalitis intensively studied in the Independence region, only 4 were in persons who gave a history of frequent colds or sore throat prior to onset of the illness, only 6 were in persons who had bad tonsils, 3 were in persons who were subject to fever blisters, 12 were in persons who during the 2 weeks or more prior to illness had unhealed wounds or sores, and 24 were in persons who had diseased gums and/or badly decayed teeth. Definite histories of mouth conditions were obtained for 18 city cases and 22 township cases. The 18 city cases were in persons who during the 2 weeks or more prior to their onsets of encephalitis had mouth conditions as follows: 10 with Riggs' disease, 2 with Vincent's angina severely affecting the gums, 4 with false teeth, and only 2 with healthy gums and sound natural teeth. The 22 township cases were in persons who during the 2 weeks or more prior to their onsets of encephalitis had mouth conditions as follows: 12 with Riggs' disease, 2 with false teeth, and 8 with healthy gums and sound natural teeth. In a sufficient proportion of instances to be somewhat impressive, the one member of a family who had a foul mouth was the one member who developed encephalitis.

Water and Foods

There was no evidence that any water supply used for drinking operated as a factor in the spread of encephalitis. The distribution of cases among users of the different water supplies was in close proportion to the numbers in the general population exposed to the different supplies.

No evidence was obtained pointing to milk or any milk product as a factor in the spread of the disease. The number of cases among the users of milk from the different milk supplies of the community was as nearly proportionate to the amount of the milk distributed by the different dealers as could be expected with such a limited number of cases. There

was no disproportionately large number of cases among consumers of milk or any other dairy product from any one source. The heavier milk drinkers and ice cream consumers of the affected families generally escaped the disease. A large majority of the cases were in persons who used milk sparingly (in coffee or on cereals) or not at all.

No evidence was obtained to suggest that meat, vegetables, or fruit, or any other food supplies were a considerable factor in the spread of the disease. Only 5 of 18 cases in the Independence group and only 4 of the 24 cases in the Blue Township group—whose histories on this point were obtained—were in persons who, within the 3 weeks prior to onset of illness, ate any food or drank any beverage of an unusual nature either at or away from home to which other members of their families were not also exposed. The incidence of the disease appeared less among beer drinkers than among nonbeer drinkers in the community, and there was no suggestively large proportion of cases among those who habitually drank beer of any one particular brand.

Sanitary and Hygienic Conditions. The large majority of the encephalitis cases were in persons residing in dwellings with apparently good sanitary and hygienic conditions, excepting that with respect to exposed sewage in the street gutters and nearby creeks.

Animals on Premises. The presence of animals at the 18 affected homes visited in the city and in 27 affected homes visited in the township was determined.

Unusual Insects. In 18 of the affected city homes visited, large gray flies of an unusual kind were reported to have been present in large numbers at 4 and small black flies at 2. In 27 of the affected township homes visited, large black flies of an unusual kind were reported to have been present at 1, bottle flies (in large numbers) at 1, and small black flies at 1.

Personal Contact. Among the 122 homes in which cases were reported in the encephalitis epidemic in the Independence region there were only two instances of more than one case in a home. Two cases occurred in one of the homes in the city and two in one of the homes in Blue Township. The interval between the on-

sets of the two cases in the city homes was 25 days and that between the onsets of the two cases in the township home was 7 days. The affected households in the zone averaged 4.5 persons. Therefore, the total number of persons who did not develop the disease in those 122 households was about 425. The case incidence in the Independence region was 1 to about 200 of population. In view of these data, it seems that residence in a home with a case of encephalitis did not increase the risk of contracting the disease.

Of the 47 cases specially studied, only 3 gave a history of direct association and only 1 of indirect association (through another member of the family) with previous cases of encephalitis, and among these 3 are included the 2 cases developing in previously affected households. Thus, it appears that if personal contact operated as a considerable factor in the spread of the disease, it must have done so in a very quiet, mysterious, and obscure manner.

The persons not developing the disease in the stricken households of the Independence region were, according to the histories obtained, remarkably free during the period of the epidemic from ailments of a sort to suggest the possibility of a mild case of encephalitis. In only 2 of the 45 households visited were histories obtained of such ailments in other members of the household. In one a son of the patient suffered with a "cold" during the 2 weeks prior to onset of the encephalitis case, and in the other the wife of the patient had an "intestinal upset" for 2 days about 1 week before the development of the encephalitis case.

Two instances were discovered of the occurrence of more than one case of encephalitis among persons at place of occupation—one at a public school in the city, where a librarian and a janitor had their onsets of illness 5 days apart, and the other at a printing office in the city, where the cashier had her onset of illness on August 22, and her successor at the desk, on August 29, 6 days after going on the job.

Biting Insects. Of the encephalitis cases especially studied, 19 city cases and 28 township cases, 9 had a history of having been bitten by insects other than mosquitoes 2 or 3 weeks prior to the onset of illness. In the city, 4 persons

had been bitten by small black flies or gnats and 1 by large black flies. In the township, 2 persons had been bitten by fleas, 1 by large black flies, and 1 by small black flies.

Every one of the persons who developed the disease gave a definite history of having been bitten by mosquitoes frequently and many times during the period of 3 or 4 weeks immediately prior to, and extending to a time within a few hours of, onset of illness. Thus, mosquitoes appeared to be the only biting insect to serve as the epidemiological common denominator to all the cases.

At each of the homes visited, the one member of the family who "did not mind" mosquitoes and who was not "poisoned" by them was the one who developed the case of encephalitis.

Discussion

The observations and reports on the encephalitis epidemic in Missouri in 1933 indicate that the flight of mosquitoes in the regions in which the disease was highly prevalent began to diminish about September 15, and by the end of that month was probably less than 10 percent of that of the period of maximum flight. Following a heavy rain and a pronounced drop in temperature in the night of September 26, both the flight and the larval life of mosquitoes suddenly decreased very much in the Independence region. Twenty-five dippings on September 28 from places in Rock Creek and in other polluted creeks in the vicinity showed only two live larvae. Every dipperful of water from those same places on September 22 had shown scores or hundreds of live larvae. Thus, it appears that the epidemic in each of the most heavily affected regions began and reached its height when and where mosquitoes (*C. pipiens*) were unusually and tremendously prevalent, decreased as the mosquito flight decreased, and ceased to prevail (in epidemic rate) when adult mosquitoes in the vicinity became scarce or ceased to travel. Such coincidences are significant.

The epidemic in Missouri this year seemed to present many epidemiological features similar to those of the epidemic in the Inland Sea

region of Japan in the summer of 1924. Mosquitoes found in the vicinity of Osaka have been identified as *C. quinquefasciatus* and/or *C. pipiens* (2). It would be interesting to ascertain whether they were unusually abundant in the Inland Sea region in the summer of 1924.

Conclusions

1. The preponderance of epidemiological evidence supports the hypothesis that encephalitis lethargica of the epidemic type which prevailed in Missouri and neighboring States in the summer and autumn of 1933 is caused by an agent (micro-organism, virus, or toxin) which is conveyed to persons by mosquitoes (*C. pipiens* and/or *C. quinquefasciatus*) which have bred under some set of unusual conditions in waters heavily polluted with human sewage, thereby becoming capable for a short period—perhaps only a few hours—of conveying the causative agent to persons by biting or otherwise without previously having fed upon the blood of a person or other living animal harboring the causative agent.

2. The installation of sewerage systems and other appropriate measures should be carried out as promptly and as thoroughly as may be practicable, before the summer of 1934, in every city, town, village, and suburban and other thickly settled community to prevent the breeding of *C. pipiens* and/or *C. quinquefasciatus* mosquitoes in surface streams, creeks, rivers, ponds, lakes, or other exposed collections of water which are or which are likely to become heavily polluted with human sewage.

3. From all the evidence obtained in the course of these studies, it appears improbable that water used for drinking and culinary purposes, milk or other foods, insects other than mosquitoes, or personal contact, either separately or together operated as very considerable factors in the spread of the disease.

4. Persons generally, and especially those over 50 years of age, in communities in which encephalitis prevails or is likely to prevail in epidemic rate should hasten to secure needed corrective work to put their gums and teeth in hygienic condition.

5. Encephalitis lethargica should be made a reportable disease by Federal, State, and local health agencies.

6. Studies of the cause and mode of spread of encephalitis should be continued unceasingly and adequately until complete practical knowledge of the subject becomes available.

EDITOR'S NOTE: *The theory of mosquito transmission of encephalitis, detailed in the foregoing paper, was touched upon briefly in a paper read by Dr. Lumsden at the 29th annual meeting of the Southern Medical Association in St. Louis, Mo., in November 1935 and published in the March 1936 issue of the Southern Medical Association Journal, vol. 29, pp. 303-308.*

Air Pollution

Wagner College. The sixth annual symposium on air pollution and its control will be held at Wagner College, Staten Island, N. Y., on Saturday, April 26, from 9 a. m. to 4 p. m.

Participating in the symposium will be air pollution control officials from government and industry, and specialists in the fields of engineering agriculture and public health.

This year's program will emphasize the legal, technical, and legislative aspects of interstate air pollution control, and the contribution of industry to the abatement of atmospheric contamination.

The symposium is sponsored by Wagner's department of bacteriology and public health. Dr. Natale Colosi, chairman of the department, is in charge of the symposium.

University of North Carolina. Concentration of course work in air pollution, offered in fulfillment of the master's degree, has been announced by the School of Public Health of the University of North Carolina, Chapel Hill. Courses are open to sanitary scientists and sanitary engineers.

The department of sanitary engineering, which has a grant from the Community Air Pollution Program of the Public Health Service, will direct the studies.

University of Minnesota. Specialized graduate courses in air pollution will be offered in the spring quarter of 1958. This summer, from August 4-15, a workshop in air pollution will be open to qualified physicians, engineers, chemists, and other sanitation personnel. Inquiries should be addressed to Dr. Gaylord W. Anderson, Director, School of Public Health, College of Medical Sciences, University of Minnesota, Minneapolis 14.

Tax Victory

The health center in Concepción, Paraguay, won a victory when the municipality dropped its building tax on latrines. The levy of 250 guaranies equaled the total construction cost of the latrine, and made the price prohibitive to many families.

—M. A. TAFF, JR., *chief, health, welfare and housing field party, U. S. Operations Mission, Paraguay.*

Second Try

The paramount chief, two clan chiefs, district commission members, and the director of public health nursing spoke at the first graduation of a class of four unlettered midwives in Gbarnga, Liberia. Only the three midwives who failed to pass did not enjoy the festive occasion. Two of them remain undaunted, however, and are enrolled in the next class of 10 pupils. Recruiting for the midwives course goes on in all important clan areas. Classes are scheduled for 8 different locations, including the Gbarnga clinic.

Pilgrims and Smallpox

After pilgrims returning from Kerbella, Iraq, introduced 21 smallpox infections in Iran, Iranian and Iraqi public health officers of the provinces along the common border met to develop a control plan. Dr. Franz Rosa, U. S. Operations Mission, Iran, visited Iraq for 5 days to help work out a joint and coordinated plan of action by the two countries to combat the disease.

Opportunities for the introduction of smallpox into Iran by Kerbella pilgrims resulted from several factors. Some travelers were not vaccinated as they left or reentered Iran. Nor were they immunized in Kerbella, where the disease has not been effectively controlled. Police and quarantine authori-

ties overlooked vaccinating or examining infants who were regarded as "baggage."

Infected ailing pilgrims were carried all the way across the country on buses; some were not even identified when they crossed through quarantine posts. Ineffective vaccination, illegal border crossings, false vaccination certificates, concealment of infected travelers, and failure to check certificates or to isolate cases also contributed to transmission of the virus.

Vaccination and quarantine measures have since been strengthened. Now only 10 percent of the pilgrims leaving the country are unvaccinated as they reach the border. Previously, a third of those returning from Iraq, having left Iran several months earlier, were not vaccinated. Every unvaccinated person that is seen at the border station is being immunized.

—GLEN W. McDONALD, M.D., M.P.H., *chief, Public Health Division, U. S. Operations Mission, Iran.*

Thai Promoter

The headman of Bang Tao, Thailand, is the strongest advocate of the privy program. After a trip to Bangkok he came back determined to promote in his own village the progress he'd seen in other parts of the country. As a result, enthusiastic participants in Bang Tao's health project have bought 300 privy slabs.

The villagers at first objected to the privies on the religious principle which forbids more than one human fecal deposit in the same place. Now installing a privy is the popular thing to do in Bang Tao. Slabs are sold at cost and the money put into a revolving fund to make additional slabs. Health department sanitarians assist in selecting sites and installing slabs.

Interest in health education and community organization ran as high in the 7 villages of Tambol Gatoo, our first demonstration area. Villagers as well as community health council members joined in the self-help project. Privy slabs have been selling almost as fast as they are produced; 500 have been installed.

Other phases of this project include protection of private and public water supplies, premise sanitation, and improvement of preventive and medical care facilities of the local health centers.

—ANDREW P. HAYNAL, *deputy chief, public health adviser, U. S. Operations Mission, Thailand.*

Oklahoma's Heart Disease Course for Multidisciplines

KIRK T. MOSLEY, M.D.

SCIENCE teaching has the responsibility of keeping workers in the field abreast of new developments. This task of communicating information to those responsible for translating scientific advances into health services for individuals, families, and communities is often complicated by the fact that this information cuts across many disciplines. Public health especially embraces a variety of services demanding broad understanding by many individuals working together to accomplish their purposes.

These people must be made to feel more competent in their own fields and to know how their services complement the services of workers in other disciplines.

Accordingly, a course on heart disease was offered at the University of Oklahoma, May 28-June 9, 1956, with the basic purpose of providing better services to heart disease patients through increasing the knowledge and skills of workers in various disciplines. The course was designed to show the importance of and give opportunities for a team approach by those with the various skills and technical abilities required to take care of the needs of the patients.

Representatives from voluntary and official agencies at local, State, and national levels participated in the planning meeting. National bodies represented were the American Heart Association, the National League for Nursing, and the Public Health Service. On the State

level those represented were the Oklahoma State Heart Association, Oklahoma League for Nursing, the Oklahoma State Health Department, and the School of Medicine, the School of Nursing, and the Extension Division of the University of Oklahoma. These State agencies subsequently became the co-sponsors of the course. Planning committee members included nurses, social workers, nutritionists, physicians, and educators.

The course of instruction, scheduled for 2 weeks, was offered by the department of preventive medicine and public health of the School of Medicine, through the Extension Division of the University of Oklahoma. Qualified students successfully completing the course received 2 hours of university credit.

Enrollment was limited to 30 with a special effort being made to enroll students representing a variety of disciplines. A total of 27 students attended all or part of the course. In this group were 8 physicians (health officers); 11 nurses, 5 of them from official health agencies, 4 from hospitals, 1 a private duty nurse, and 1 from a heart clinic; 4 dietitians; 1 nutritionist; and 3 social workers. Attendance at some sessions, counting resource persons from contributing agencies, rose to 50.

The faculty was provided by the School of Medicine and the School of Nursing of the University of Oklahoma, the Oklahoma State Health Department, the American Heart Association, the Oklahoma State Heart Association, and the Public Health Service.

The Oklahoma State Heart Association and the Oklahoma Department of Health each sponsored 15 tuition scholarships, and the lat-

Dr. Mosley is chairman of the department of preventive medicine and public health, School of Medicine, University of Oklahoma, Oklahoma City.

ter in addition paid for the maintenance of all department employees who attended. Secretarial help was provided by the heart association, the university, and the health department. Literature, films, slides, and mimeographed materials were provided by the heart association and health department. Classroom and other visual aid equipment was supplied by the medical school.

Instruction was offered in a variety of ways with emphasis placed on student participation and teamwork. Field visits, special conferences, and clinics occupied the morning sessions. After lunch the entire class assembled to hear lectures on subjects dealing with the physiology of the circulatory system, etiological factors and preventive aspects of heart diseases, and recent advances in research on the cardiac disorders. Following the lectures, students met in small groups for discussion and exchange of information about the field experiences in which they participated during the morning period. At a seminar session held the last hour of the day, students had an opportunity to discuss with a panel of appropriate experts a selected phase of the heart disease program.

Field Experience

For the field experience, one of the most successful aspects of the program, the class was divided into 5 small groups, each with students from 2 or 3 disciplines. Each member of a group was assigned a different type field activity each day, and no two members of the same group participated in the same activity together. For example, during a morning period, one member of a group might be assigned to observe bedside nursing care of a cardiac patient in a hospital, another member to accompany a public health nurse on a home nursing visit to a cardiac patient, a third member to visit the vocational rehabilitation office for a conference on the role of this agency in the rehabilitation of cardiac patients, and a fourth member to visit the food clinic and confer on diets for cardiac patients.

This arrangement provided the group with varied experiences and encouraged the exchange of information between group members.

Among the institutions and facilities visited as a part of the field experience were the Oklahoma Medical Research Foundation, Oklahoma State Heart Association, Department of Public Welfare, State Industrial Commission, physical medicine department of the Oklahoma School of Medicine, Crippled Children's Commission, a nursing home, cardiac catheterization clinic, medical wards, social service and dietetics departments of the University Hospitals, cardiac conferences for children and for adults, heart station where electrocardiographic examinations are made, rheumatic fever clinic, and a convalescent hospital. During the visit students were given an opportunity through discussion and conference to obtain a better understanding about the role of the agency or facility in providing services to heart patients.

"Handout" Materials and Tests

Three portfolios, Social Service Information, Nursing Information, and Nutritional Information, were distributed to each member of the class. Each of the portfolios contained 8 to 10 pieces of literature which had been obtained from the Public Health Service, heart association, or other sources. In addition to the literature, a carefully selected bibliography which included visual aid material was distributed. Thus, each student could take home from the course the most recent literature available for the various disciplines.

Tests before and after the course were given to gauge student progress. These tests comprised hypothetical family situations based on case material from the University Hospitals and health department files. The individual responses uniformly indicated an increasing knowledge about heart diseases and the problem of patients with heart diseases. The answers also revealed an increased awareness of the need to coordinate the services of professional workers responsible for the care of cardiac patients. The results of the tests reflected definite achievement toward the chief objective of the course, better care for the heart patient.

Followup Conferences

Approximately a year after the course, about 14 persons met with one of the instructors from

the Public Health Service for a followup conference. Through this group approach an attempt was made to get tangible evidence of the value of the course expressed in terms of better patient care. The remainder of the class were contacted by letter. These are some of the experiences reported:

- A nursing supervisor, who participated as a resource person, reported she had had a feeling of frustration after the course because she had been made aware that nurses in the hospital were not "nursing the patient." She is now director of the Baptist School of Nursing in Oklahoma City.

- A private duty nurse, who for 1½ years had been caring for a patient with cirrhosis of the liver, said she understood better how to give her patient, a physician, a low sodium diet. The nurse prior to going on duty with her current patient had for 2 years taken care of cardiovascular disease patients only.

- A hospital dietitian, who is now an instructor in a school of nursing, reported that she had prepared teaching materials centered on the patient with cardiovascular disease rather than on the diet.

- One medical social worker, serving on a national committee, felt she was more helpful in selecting teaching materials for schools of social work. She had been active also in establishing communication between the new medical

social worker in the school of medicine and those in other disciplines.

- One of the health officers said that during the course he had learned for the first time that State health department nutritionists were interested in the problems of special diets for the cardiovascular disease patient and had begun using their services. Recently, he became the assistant to the director of the division of local health services in the Oklahoma Department of Health and now is serving as consultant throughout the State.

In Tulsa a different approach was used. The supervising nurse had shared her course of instruction with the nurses in the district to which she was assigned. These staff nurses reported their experiences to the group. One nurse asked a private physician regarding dietary problems of the patient for whom the physician had requested nursing service in giving a diuretic. At first the physician rejected the idea; later he acknowledged the visiting nurse's contribution by requesting visits to other patients. Nurses in other supervisory districts felt that they too would have benefited by instruction from the supervisor who attended the course session.

This followup evaluation added much to the significance of the course and provided useful information in planning future courses of instruction.

How to Set Up a Heart Course

For schools wishing to offer a heart disease course for multidisciplines similar to the one at the University of Oklahoma, the Heart Disease Control Program of the Public Health Service has prepared the following outline describing step by step the development of the course. This outline may serve as a checklist; however, it is only suggestive since individual situations cannot be anticipated, and its chronology cannot possibly be more than relative.

ASSUMPTIONS

That the course will be held at an established university or college for a minimum period of 2 weeks.
That an approximate number hours of credit in the school will be given, if desired, to those who are eligible.

That a properly representative committee will take the leadership in effecting the course.

That the whole-hearted cooperation of all the necessary participant agencies will be attained.

That the need for, and interest in, the course will have been determined in advance.

ter in addition paid for the maintenance of all department employees who attended. Secretarial help was provided by the heart association, the university, and the health department. Literature, films, slides, and mimeographed materials were provided by the heart association and health department. Classroom and other visual aid equipment was supplied by the medical school.

Instruction was offered in a variety of ways with emphasis placed on student participation and teamwork. Field visits, special conferences, and clinics occupied the morning sessions. Some Epidemiological Aspects of Cervical Cancer

RAYMOND F. KAISER, M.D., and ALEXANDER G. GILLIAM, M.D.

EPIDEMIOLOGY is concerned with study of disease in human populations. In common with other medical sciences, its objective is to determine the factors related to or governing disease occurrence. Unlike other medical sciences, however, its universe of study is the human population or segments of it. Through observations of human experience it attempts to determine the characteristics of those people who develop disease, and of those who escape it. This, in turn, involves the measurement of risk to disease in groups of people with different characteristics.

Epidemiological methods of measuring risk to cancer, and other presumably noninfectious processes, have for the most part been borrowed directly from techniques of proved usefulness in communicable disease study. To a large extent these techniques have been dependent upon the stage of development of other disciplines of medical science. For example, it required relatively simple observations in human experience prior to the birth of the science of bacteriology to demonstrate beyond reasonable doubt that diphtheria was communicable. An understanding of important aspects of its natural history, however, had to await the development of simple and inexpensive laboratory tests which would detect those persons in-

fectured but not sick and would evaluate the relative immunity status of the population.

In cancer, observations in human experience were directly responsible for the beginning of what has developed into an enormous amount and variety of experimental research. The first experimental cancers were produced by painting tar on rabbits' ears, an undertaking prompted by the observation in humans that risk to cancer of the scrotum appeared to be excessive in chimney sweeps. Until the development of the Papanicolaou vaginal cytology test (1, 2), however, laboratory research had provided no tools for the epidemiologist to use in extending our present relatively crude descriptive epidemiology of cancer. While it is true that cervical biopsies were introduced as long ago as 1878 by Ruge and Veit (3), it is, to say the least, impracticable to attempt cervical biopsies on large numbers of apparently well women. Though the Papanicolaou test does not satisfy all of the requirements desired by the epidemiologist, it is the first simple, acceptable laboratory test which can be applied to large numbers of well women and will select for further diagnostic evaluation most of those with cervical cancer.

Before this test could be used effectively in general epidemiological studies, a number of questions had to be answered. Could it be effectively applied in general population groups of apparently well women? What were its limits of specificity and sensitivity in such groups? What were the practical logistical problems?

Dr. Kaiser and Dr. Gilliam are both with the National Cancer Institute, Public Health Service, serving as chief and assistant chief, respectively, of the Field Investigations and Demonstrations Branch.

That all of the requisite resources, both human and material, are available and can be fully utilized.

PRELIMINARY PHASE

Appoint a "heart course" steering committee.
Establish overall objectives.
Select a course coordinator.
Choose nonconflicting dates.
Nominate faculty members and verify their acceptance.
Assign responsibility for media publicity.
See that participating agencies are personally briefed.
Determine number and disciplines of students.
Arrange for classrooms, housing, meals, and transportation, as necessary.
Determine the financing of the course: tuition and registration fees, selective scholarships, and so forth.

INTERMEDIATE PHASE

Determine course content, teaching methods, and format.
Explore clinical facilities available for field experience and observation.
Arrange for selected patients to be observed.
Prepare and mail announcement brochures to predetermined list of prospective students.
Choose and obtain visual aids and equipment.
Check availability of library facilities for reading assignments.
Assemble family and patient summaries from live case material selected from agencies sending students.
Appoint a qualified writer to prepare proceedings of the course for subsequent publication.
Arrange for secretarial and other such assistance.
Prepare detailed schedule of classes, conferences, and observations which permits flexibility in meeting individual needs.

FINAL PHASE

Prepare bibliographies, and select "hand out" literature.
Prepare sheet of suggested problem areas for group work.
Provide guide questions for observations.
Prepare pretests and posttests, based on point 7 in "Intermediate Phase."
Prepare a course "opinionnaire" for students.
Supply applicants with advance reading assignments as desired.

COURSE BEGINNING

Register students and distribute necessary instructional materials.
Divide class into teams, each to include various disciplines.
Permit each team to select a problem to study.
Provide each team with a full-time counsellor, or consultant.
Give students pretest.
Obtain from students written statements of individual objectives in the course.
Follow up on media publicity.
Throughout course allow for group decisions and flexibility indicated by student reactions.

COURSE ENDING

Give posttest.
Distribute "opinionnaire" for completion.

POSTCOURSE

Arrange for on-the-job followup of students to identify tangible results from the course.
Reassemble group for followup evaluation conference if possible.
Make resultant improvements in subsequent courses

riphery of infiltrating lesions (9). The relationship is also inferred because of its demonstrated presence prior to the development of some invasive cancers (9-12), and its detection at an earlier average age than usually observed for invasive cancers at this site (4, 9). The determination of the relationships of the carcinoma-in-situ lesion to classical cervical carcinoma is of paramount importance. To accomplish this, questions primarily epidemiological in nature must be answered.

Some of the more fundamental questions involved in this relationship are:

1. Do all invasive cervical cancers begin as intraepithelial lesions? If not, what percentage do?
2. Do intraepithelial lesions invariably progress to invasiveness? What percentage do?
3. What is the time required for an intraepithelial lesion to progress to invasiveness?
4. Do some intraepithelial lesions regress and disappear? How often does this occur?
5. Is it possible for an intraepithelial lesion to remain noninvasive indefinitely?
6. What are the age-specific incidence and prevalence rates of carcinoma-in-situ and invasive carcinoma? Are there race-specific variations in such rates?

Whether or not all invasive cancers of the cervix pass through the in-situ stage, and whether this intraepithelial lesion is reversible or always progresses to invasiveness, is not known at the present time. Its recognition, however, besides introducing problems regarding treatment (13), has opened new avenues for study of the essential pathogenesis of cervical cancer (14).

A large part of the attention now devoted to intraepithelial lesions of the cervix may be attributed to the extensive use of the cytological technique of Papanicolaou. By means of this test definitive diagnostic procedures may be directed to those women who are considered most likely to harbor invasive cancer (4). In addition, the test leads to the histological diagnosis of many intraepithelial lesions which otherwise would have remained undetected.

Clinically, the onset of carcinoma of the cervix is generally characterized by an absence of alarming symptoms. Those which would lead to its early discovery may give no concern

to the patient during menstrual life. As a result, it frequently progresses into a moderately advanced disease before discovery, and early carcinomas of the cervix (stage I) make up only about 10 percent of the cases seen in many clinics (15). In addition, stage for stage, carcinoma of the cervix carries a much poorer prognosis than cancer of the body of the uterus.

The League of Nations' clinical classification of these cancers, adopted first in 1929 and modified in 1937 and in 1950, divides the disease into five stages. Stage 0 is reserved for carcinoma-in-situ and the remaining four stages are reserved for progressively extensive stages of the invasive disease. Patients treated in stage 0 should respond with uniform cure. According to Heyman (15), survivorship thereafter becomes progressively worse as treatment is instituted in advanced stages of the disease; there is about 60 percent recovery for stage I and 8 percent recovery for stage IV. Results from treatment in different clinics vary considerably, but factors responsible for such variation cannot be fully assessed. It is clearly evident, however, that the stage of disease at the time treatment starts is of paramount importance in cure. This fact emphasizes the necessity for obtaining a full understanding of the quantitative relationship of carcinoma-in-situ to invasive cancer of the cervix.

Extent of Uterine Cancer Problem

With the exception of the single year 1914, deaths in the United States attributed to cancer of the uterus were grouped with cancers of all female genital organs until 1930, when the fourth edition of the International List of Causes of Death came into use. Since then, uterine cancer deaths have been tabulated annually by age and race (16, 17). Analysis of these data shows a consistent decline in the age adjusted death rates for uterine cancer among white women since 1914 and among the non-white since 1930 (unpublished data, A.G.G.).

Death data for cancer of the cervix were first listed separately in 1939, but were not subdivided by age and race until 1949. Such data are of little practical value, however, in assessing the forces of mortality from cervical cancer, since such a high proportion of all

What was the cost in money, equipment, and personnel? Although some of these and other questions have been answered with regard to use of the test as a diagnostic adjunct in clinic and office practice, the only answer to its practicality in general epidemiological study, or as a cancer control measure, lay in an attempt to use it on a communitywide basis. Recognition of this fact led to such a study in Memphis and Shelby County, Tenn. The study was instituted in July 1952 as a joint endeavor of the University of Tennessee, the National Cancer Institute of the Public Health Service, and a host of other individuals and agencies.

Many important facts have already emerged from this study (4). Sufficient preliminary data are now available for examining other facets. It is the intent of this presentation to provide a brief background of the disease itself and some descriptive facts and apparent facts of the epidemiology of cervical cancer.

The Disease Itself

Carcinomas of the uterus may be classed in three groups: epidermoid, or squamous cell, carcinoma of the cervix, endometrial adenocarcinoma of the corpus, and adenocarcinoma of the cervix (5). Epidermoid carcinoma of the cervix and adenocarcinoma of the corpus appear to be quite distinct entities in histological structure, clinical behavior, and selective factors associated with their occurrence. Adenocarcinomas of the cervix are less clearly differentiated from the other two groups because of the difficulty in determining the precise point of origin of some adenocarcinomas of the lower part of the uterus.

The relative frequency of the 3 types of uterine carcinoma varies considerably from one reported series of cases to another, but broadly speaking cervical carcinoma is 3 or 4 times as common as endometrial, and cervical epidermoid carcinoma is at least 10 times as common as cervical adenocarcinoma (5).

At least some, and conceivably a large part, of the differences in relative frequencies of fundal and cervical carcinoma, as reported in different series of cases, is due to the different composition of each series with respect to age, race, marital status, and other selective factors

associated with the occurrence of the two diseases. Most published series do not provide the data on such characteristics, which are necessary to make adequate appraisal of the large differences in recorded relative frequency.

Most epidermoid carcinomas of the cervix arise directly from the stratified epithelium of the external os or the portio vaginalis. Occasionally the origin may be from metaplastic stratified epithelium formed within the cervical canal or glands, or in an endocervical polyp (5). The development of the disease in the cervix is not dependent on the presence of the body of the uterus since it occurs after subtotal hysterectomy performed for other uterine disease. While occasional specimens of early cervical carcinoma afford evidence that the growth has arisen, not from a single minute focus, but from a considerable field of epithelium, no clear instances of genuine multicentric origin have been described (5).

In addition to frankly invasive malignant lesions of the cervix, histological lesions have been described since 1910 which fulfill all criteria of malignancy except invasion (6). As a result of his work with the colposcope, Hinselmann, as quoted by Traut and Benson (7), described in 1924 four classes of lesions of abnormal cervical epithelia from dysplasia through anaplasia, and intraepithelial cancer to invasive cancer. The term carcinoma-in-situ was applied to the most definitive of these patterns of abnormal epithelium in 1932 (8). Since then, this lesion has been variously labeled surface carcinoma, intraepithelial carcinoma, intramucosal cancer, and carcinoma-in-situ. It is now generally agreed that it may be preinvasive cervical cancer or an early stage of cervical carcinoma. However, there is considerable controversy as to the significance of other epithelial changes, such as dysplasia, hyperplasia, and anaplasia, and their possible relationship to invasive carcinoma.

Since 1932, much literature has appeared concerning the minimum histological criteria necessary for diagnosis of carcinoma-in-situ, as has data on its frequency, incidence, and its significance. Its relation to invasive cancer is inferred because of its histological appearance (6) and, according to Schottlaender and Kermanner, because of its occurrence at the pe-

in either Denmark or Memphis (30). These regional differences in age selection are sufficiently great to warrant the suspicion that they are not artifacts, but no ready explanation is available for them. Further, in each locality, fairly distinct differences exist between the age selection of cancer of the cervix and of cancer of the body of the uterus. The consistently different age selection of cancer in the two parts of the uterus is one reason for suspecting that they represent two disease entities.

Race Selection

With the exception of limited morbidity data, and fairly extensive mortality figures for the white and nonwhite population of the United States, most of the evidence of racial selection of cervical cancer is derived from relative frequency data. Relative frequencies on some occasions faithfully reflect absolute variations in risk, but on other occasions they do not. In any case, there is probably no other type of cancer in which racial selectivity of the disease, as suggested by relative frequency evidence, offers such intriguing possibilities of better understanding its genesis.

On the basis of relative frequency figures, Williams claimed in 1900 that American Negroes were less prone to uterine cancer than white women (21). That the reverse is true is now amply demonstrated not only by mortality figures for a long period of time but by morbidity rates collected in special surveys (28, 29). Many doubt that the clearly excessive risk among the nonwhite women in the United States is due to actual racial susceptibility. Most workers contend that it is due instead to a number of factors which have been loosely classed as social or environmental (30, 31).

While the early relative frequency evidence for the white and the nonwhite women in the United States was not substantiated, evidence of a similar basic nature relating to Jewesses has been established as correctly portraying relative risk (30). There appears to be no longer any doubt that Jewesses experience substantially less risk to cancer of the cervix than the non-Jewish (32, 33, 35). A recent study in Israel has elicited very low incidence rates, and since Jewesses of different "ethnic typology"

experience rates of about the same magnitude, the authors believe that it cannot be dependent on a racial factor, but is due instead to circumcision of Jewish males (35).

Except for absolute comparisons of risk relating to the white and the nonwhite population in the United States and Jewesses in Israel, most of the other evidence of racial selection involves relative frequency data. For example, Khanolkar's study relating to various classes of Indians attending the Tata Memorial Hospital in Bombay supports the idea that Hindu Decanni and Gujarti, and Moslem women, all experience a different risk to cancer of the cervix (36). Since, however, the evidence consists of relative frequencies, not incidence, it does not establish these differences.

Mortality statistics from different countries cannot be easily compared because of the different proportions of deaths in each country which are unspecified as to portion of uterus affected. For cancer of the uterus as a whole, however, the age adjusted death rate in 1950 in Japan was more than twice that recorded in England and Wales; about 40 percent greater than the rate among white American women; and about 40 percent less than that recorded among American nonwhite women (37).

Among the American Navajos, if relative frequency comparisons are accepted as evidence, risk of death from all uterine cancer would be twice that observed in American whites and about the same as noted in nonwhites as a whole. Adequate comparisons of absolute risk show, to the contrary however, that the risk for the Navajo is only half that observed for the whites and only a fourth of that noted for the nonwhites (38).

Geographic Distribution

Data on geographic distribution of cervical cancer consist of official mortality statistics, the results of summations of autopsy series, and morbidity surveys conducted in a few localities. While the data from only the latter are reliable as to the absolute probability of developing the disease, official mortality statistics and autopsy studies clearly show that cancer of the cervix has been recorded on every continent, in every large country, and among every important ra-

uterine cancer deaths are unspecified as to the portion of the uterus affected. In 1949, 43 percent and in 1955, 34 percent of all uterine cancer deaths were unspecified as to origin in the uterus. It is therefore not possible to determine whether or not cancer of the cervix and cancer of the corpus have participated equally in the decline in mortality attributed to cancer of the uterus as a whole.

During 1955, 15,170 deaths were attributed to cancer of the uterus in the United States (17). Among white women the crude death rate was 17.0 per 100,000 population. This rate was exceeded by only those for cancer of the breast (27.2 per 100,000) and cancer of the large intestine (17.5 per 100,000). Among non-white women more deaths were attributed to cancer of the uterus than to any other type of cancer, the crude death rate being 28.7 per 100,000 population. For both races combined, deaths from cancer of the uterus were exceeded by only cancer of the breast. According to unpublished data (A.G.G.), on the basis of rates for deaths from all causes recorded in 1955, 1.8 percent of white and 3.0 percent of nonwhite women would be expected to die eventually of cancer of the uterus.

Of those deaths for which the part of the uterus first affected was recorded on the death certificate, there were, in 1955, 17 times as many cervical as corpus cancer deaths among the non-white and 7 times more cervical cancers among the white. As pointed out, however, there was a substantial number of deaths among both races with unspecified origin of the disease in the uterus. In the unlikely event that all of those unspecified had arisen in the corpus, deaths due to cancers of the cervix would still predominate in both races, and the cervix-corpus ratio would still be greater in the non-white than in the white.

During this period of decline in mortality, the incidence of the disease has been increasing in at least one State. In New York, between 1942 and 1953, the cervical cancer incidence rate increased 7 percent, and cancer of the corpus, 21 percent (18). In Connecticut, on the other hand, the incidence of cervical cancer decreased 8 percent while corpus cancer increased 22 percent between 1935 and 1951 (19).

Based on reports from New York State, during 1949-1951, the lifetime probability of developing cervical cancer was 2.2 per 100 women, and cancer of the corpus, 1.5 per 100 women, or a total of 3.7 per 100 women for all uterine cancer (20).

Age Selection

The tendency of cancer of the cervix to occur earlier in life than cancer of the body of the uterus was well known at least as early as 1900. In Williams' series the maximum frequency was in the age group 35 to 45, as compared with the mode in the age group 50 to 60 for cancer of the corpus (21). While cases in persons under 20 years of age are uncommon, a few histologically diagnosed cases have been described in such persons (22-24), the youngest being an infant of 7 months with a cervical adenocarcinoma (25). In 1955, out of 8,504 deaths attributed to cancer of the cervix in the United States, 3 were under 5 years of age and 5 under 20.

Perhaps the most reliable data on age incidence of the disease are those from Denmark and Sweden. These data reflect the annual probability that women of various ages will develop or be diagnosed as having the disease. In Denmark, for the years 1942-44, the incidence rates for cancer of the cervix rose sharply from age 25 to a peak of about 70 per 100,000 in the age group 45-49, and declined fairly regularly thereafter (26). In Sweden a similar age selection is evident though the rates, age for age, are lower than observed in Denmark, and the peak of incidence occurs about 5 years later in life (27). The Swedish data also show a regular increase in incidence at all ages between the calendar years 1925 and 1945, an increase more marked than that observed in New York State.

In contrast with the type of age selection prevalent in Denmark and in Sweden, risk of the disease in Connecticut increases fairly regularly with age, and instead of declining after 45 or 50 continues to increase, reaching a peak in women 85 and over (19). A similar type of age curve is observed among white women in Shelby County, Tenn., but not among the non-white (28). In New York State the age selection is somewhat different from that observed

observed between breast and cervical cancer patients in any 1 of the 3 localities.

It appears clear from the brief considerations mentioned that the role of these various factors associated with cervical cancer still remains to be clarified with additional and perhaps different kinds of systematically collected data.

Socioeconomic Status

It has been common experience of gynecologists that cancer of the cervix is less frequently encountered in private than in clinic practice. Mortality data for 1930-32 for Great Britain similarly indicated that risk of dying from uterine cancer as a whole increased with the decrease in socioeconomic status (53). That this is largely due to cancer of the cervix is now evident from analysis of similar death data for 1950 and 1951 (46). These show that when socioeconomic class is judged by occupations of husbands, the rates were lowest in women whose husbands were in the professional class and highest in wives of unskilled laborers, with a fairly regular gradient in the intermediate classes. Stocks concludes from these and other analyses of regional variation in mortality that the disease in Great Britain shows a relationship with overcrowded housing, social class distribution, and predominant industry 20 years before (46).

Infections and Cervical Lacerations

For a considerable period of time, chronic cervical infections and poor obstetrical care were believed to predispose a woman to carcinoma of the cervix. The idea that cervicitis or cervical lacerations might be the cause of this cancer is probably an outgrowth of the general theory of chronic irritation as the cause of all cancer. There appears to be little definitive evidence bearing directly on it one way or the other, however. From the histological standpoint, early cancers at this site are observed with no associated evidence of chronic irritation. Evidence of cervical lacerations, on the other hand, is common in parous women.

Gagnon is of the opinion that the rarity of the disease in nuns is due to the infrequency of cervicitis in this group (51). Cashman has

noted that fewer cervical cancers than expected occurred in about 5,000 women who could be followed out of 10,000 women whose cervicitis had been treated by deep cauterization (54). If, however, there had been a very few cases among those women who were not followed, the results might have been quite different.

With regard to cervical lacerations, Lombard and Potter's case history study indicated an association between history of lacerations and this cancer (47). Gilliam's series, on the other hand, at least indicated no undue proportion of instrumental deliveries among cervical cancer patients (48). Since both studies depended upon histories as remembered by patients and controls, it is not certain that they correctly portray the actual facts. As for other evidence based on clinical impressions, there is still considerable difference of opinion among gynecologists as to the possible association of these factors and the disease. That even repeated trauma, and by inference cervicitis, is not necessarily involved is suggested by the apparent rarity of the disease in cases of prolapsed uterus (55).

Discussion

It should be clear from this brief account of some of the facts of distribution of cervical cancer among humans that many selective factors bearing on its occurrence have been recognized. There is a common, and perhaps unfortunate, tendency among students of cancer, however, to assign specific causal significance to such factors, often even before the facts themselves are well established. Thus, when it appears that cervical cancer is more common in parous than in nulliparous women, the statement soon after appears in texts, as though it were fact, that the disease is caused by cervical lacerations. When it is evident that Jewesses are less prone than the non-Jewish—then *ergo*, it is caused by intercourse with the uncircumcized. Or, when it appears there is a tendency to select women who marry early in life—it is caused by trauma of immature tissues. Or, when it is shown that risk is greater in syphilitics than in nonsyphilitics—it is caused by chronic irritation. Or, because it selects the lower rather than the higher economic classes,

cial and ethnic group. Furthermore, the frequency of cancer of the cervix relative to all other cancer, as observed in the autopsy series, varies considerably from place to place. Whether or not risk of the disease varies in the same fashion cannot be determined from most such studies.

Within some countries for which pertinent data are available, incidence of the disease varies considerably. In Denmark the highest rates are observed in Copenhagen, and the lowest among the rural population (39). This excess risk among urban women also appears to exist in the State of Iowa (40). White women in southern cities of the United States appear to experience greater risk than do the northern white women (29), and in Copenhagen (41) and Pittsburgh (42) there is considerable variation in rates within the city. In these latter cities the higher rates are found in the poorer sections.

Marital and Pregnancy Status

The first clear evidence that cancer of the uterus and cancer of the breast tend to have an opposite selectivity with respect to marital status was presented apparently by Rigoni Stern in 1842. While only 6 percent of the uterine cancer deaths recorded in Verona, 1769 to 1839, were in unmarried women, 29 percent of the breast cancer patients were unmarried (43). These differences are the more striking in view of the fact that cancer of the uterus generally occurs at an earlier age when the probability of marriage is less than in later life. These data did not permit the firm conclusion that uterine cancer is more likely to occur among married women than among single, but they did demonstrate the striking difference from breast cancer in terms of selectivity according to marital status.

It has now been established that the annual probability of developing cancer of the cervix is greater in married than in single women (39, 44-46). It would further appear that early age at marriage and instability of marriage are also associated with this disease (47, 48). In addition, there is some reason for believing that other variables associated with instability of marriage are also associated with cancer of

the cervix. Thus, there is scattered evidence that illegitimate births (48), syphilis (29), early sexual relations, multiple sexual partners (37), and prostitution (50) are all associated with this disease. On the opposite side of the coin, cervical cancer appears to occur very rarely among nuns (51).

Another variable associated with marriage, which has been given much consideration, is circumcision of the marital partner. This was due first to the observation that cancer of the cervix is less frequent among Jews, where circumcision is universal. Other races which practice circumcision at varying ages and to a different extent are alleged to have varying risk of cervical cancer. The so-called incidence reported for such races, however, is invariably a relative frequency which may or may not reflect relative risk to this cancer. Reliable data on the incidence of cervical cancer are very badly needed among such groups as the Moslems, Hindus, Bantus, and Fijis. Such rates can now be reliably and relatively inexpensively ascertained through discriminative use of the vaginal cytological technique.

Another variable which has long been associated with cervical cancer is pregnancy. Lane-Claypon's (52) data indicated an association between pregnancy, but not number of pregnancies, and cancer of the cervix. Malphrant's series (44) suggested the greatest risk in parous women, with each pregnancy adding slightly to the risk; the next greatest risk among childless married women; and a considerably reduced risk among single women. Logan's analysis of British mortality data suggested that marital status alone, apart from childbearing, seemed to be the factor associated with higher mortality (45). In Gilliam's series where a precise actuarial method was used in computing age specific pregnancy rates in several types of cancer patients, the difference in fertility between those with breast cancer and those with cervical cancer was limited to the first 30 years of life (48). After age 30, pregnancy rates in breast and cervical cancer patients were identical. A further curious finding in this series was the greater difference in pregnancy rates between the cervical cancer patients interviewed in 2 of the cities than was

it is caused by poor hygiene and inadequate general medical care.

All of these factors associated with cervical cancer may well eventually turn out to be causes. On the other hand, an equally tenable hypothesis at the present time is that the disease is caused by some presently unknown factor or patient attribute which is more commonly present in women with these characteristics, but is by no means limited to them. The fact remains that the disease does occur in virgins, in nullipara, in Jewesses, in the non-syphilitic, and in women of the highest economic classes, to mention only a few of the selective factors. Demonstration of excessive risk in women with certain characteristics does justify a hypothesis. No useful purpose is served, however, by parading hypotheses as fact, a tendency all too commonly encountered among students of cancer in general.

Up to the present we are aware of no weaving together into a coherent and generally satisfying explanation of the disease the threads of facts regarding distribution of cervical cancer in humans. The development of the Papanicolaou test, however, provides a laboratory tool which, if properly exploited epidemiologically, can at least test and either dispose of or extend some hypotheses which have been paraded as fact.

animals and insects in man's environment, dogs, cats, rodents, flies, ticks, snakes, and tortoises have been incriminated as vectors of salmonellosis. *Salmonellae* have also been isolated from fish and shellfish, and the evidence indicates that these species encountered the organisms in water contaminated by man or other non-aquatic animals.

Since *Salmonella* types are widely distributed through the animal kingdom, there is small wonder that the organisms are frequently present in animal food products. Recent investigations have revealed their presence in an unexpectedly high percentage of meat and animal products, and this has resulted in a further investigation of the roles that food processing and human carriers have in salmonellosis. Carcasses in abattoirs have been shown to contain organisms more often than animals on farms, indicating that the abattoir environment and processing procedures favor the spread of the organisms. Investigators have also found salmonellae widely distributed in poultry-processing plants.

Although outbreaks in which human carriers were responsible for the contamination of meat products have been frequently described, the ultimate source is in no way certain since it might be said that the carrier state is an occupational hazard of those who continually handle uncooked meats and carcasses. Direct transmission may also occur from man to man without the intervention of food.

Means for control of the incidence and transmission of salmonellosis are slowly getting under way.

While there is a large reservoir of salmonellae in the lower animals, this situation can be expected to improve gradually. Tests for the detection of the infections and methods of eradication are being studied in fowl and cattle. Progress has been made in the eradication of salmonellae from poultry flocks through agglutination testing programs for *Salmonella typhimurium*. Possibilities of detecting *S. dublin* infection by agglutination tests have also been studied. Although the elimination of salmonellosis from flocks and herds cannot be accomplished in the immediate future, it is encouraging that animal pathologists are thinking of eradicating the infections rather than

controlling them. It must be admitted, however, that this attitude is directed largely by economic considerations rather than by regard for public health.

In any effort to eradicate salmonellae from domestic animals it is necessary to take into consideration the continuous seeding of the population through infected feed, and such sources must be eliminated if *Salmonella* infections are to be eradicated from flocks and herds.

With regard to dissemination from person to person, every effort should be made to prevent the spread of organisms among the population by means of the excreta of patients, convalescents, and carriers. This is a joint responsibility of the practicing physician, the health officer, and the laboratory. Prompt isolation of patients with symptoms of intestinal infections and proper disinfection of the dejecta must be carried out until such time as a definite diagnosis is established. Contacts should be examined bacteriologically, and the strictest personal hygiene should be practiced in the household. Convalescents should be examined systematically until the bacteria no longer can be isolated from the excreta.

Stool cultures should be required from all food handlers, not only those in food dispensing establishments but those in food processing plants as well. In addition, hygienic conditions in these plants and establishments must be improved. It has been demonstrated that thorough and consistent cleansing of abattoirs and equipment results in a marked reduction in the recovery of salmonellae from carcasses and from the environment.

Researchers have suggested that bacteriological standards for the control of abattoir and food processing establishments would be helpful; that an approach similar to that employed in dairy products should be applied to other products of animal origin including fish and poultry; and that, in time, coliform organisms as an index to pollution may be successfully adopted for the bacteriological environment of meat processing plants as it has been adopted successfully in dairy products and shellfish.

Food technology has made giant strides within recent years, especially in the removal of food preparation from the family kitchen to

Animal Diseases and Human Health

On September 11–13, 1957, a Conference on Animal Diseases and Human Health was held in New York City under the joint auspices of the New York Academy of Sciences and the Public Health Service's Communicable Disease Center.

The significance of these diseases was discussed from two viewpoints: the direct transfer of disease by parasites or by consumption of diseased meat and milk, and the reduction of food supplies caused by outbreaks of animal disease.

Enzootic, epizootic, and zoonotic diseases were considered, along with means by which the diseases are transmitted. Some were examined because they present particular economic and public health threats; others because the study of animal diseases may enlighten students of human afflictions.

The conference discussions are represented here in summaries of 16 of the papers. The full proceedings are to be published by the New York Academy of Sciences.

Salmonellosis: Incidence and Control

P. R. EDWARDS,
*Communicable Disease Center,
Public Health Service,
Atlanta, Ga.*

It is impossible to determine the incidence of salmonellosis in either man or animals. No systematic method of reporting salmonellosis of animals has been established, and one must rely on summaries of isolation and identification of causative agents dispersed throughout the medical and veterinary literature to estimate the frequency with which the bacteria occur among the lower animals.

Means of determining the incidence of the disease in man are practically in the same condition. Summaries published by the National Office of Vital Statistics are based on woefully inadequate reporting from a minority of States, and in most instances the etiological agents of foodborne infections are not accurately determined. Despite these deficiencies, one must rely

upon these summaries for any estimate of the prevalence of *Salmonella* infections in the United States.

Despite methodological inadequacies with regard to incidence, the list of occurrences indicates that there is a direct correlation between salmonellosis of animals and man in any given locality, although the methods whereby the organisms are transmitted from animals to man and vice versa may vary from one region to another, depending upon sanitary facilities and habits of the population.

Numerous *Salmonella* serotypes have been isolated from animals used as food by man and from animals with which man comes into close contact. Not only have host-adapted types such as *Salmonella dublin* in cattle and *Salmonella choleraesuis* in swine been found frequently, but large numbers of types not adapted to specific hosts occur among domestic animals. While salmonellae are particularly numerous in swine, birds probably constitute the largest single reservoir in animals. The organisms have been isolated from turkeys, poultry, wild game, and egg products. Among the nonedible

indicate that transmission can be effected by inoculation of sheep with sterile centrifuged extracts of infected and frozen sheep lung. Although 1 to 3 years are usually required from the time of inoculation until symptoms appear, the disease develops progressively. Sheep sacrificed periodically after inoculation show pathological changes at least several months before symptoms are expected to appear.

Apparently pulmonary adenomatosis in sheep was entirely enzootic until early in the present century when epizootic disease appeared, inviting recognition of its contagious nature. Forms of pulmonary adenomatosis of similar histology and clinical course also occur in man. Whether etiological similarities obtain is an unanswered question at present. Information gained from the study of contagious animal neoplasm, however, may be useful as a guide to the future study of neoplasia in man.

Cat Scratch Disease

JAMES E. PRIER,
*Merck Sharp & Dohme,
West Point, Pa.*

The specific entity known as cat scratch disease, cat-bite fever, benign inoculation lymphoreticulosis, nonbacterial regional lymphadenitis, and so on, has been recognized as a common human disease only during the past decade. Actually, the condition was recognized as early as 1930 by Foshay in Cincinnati, Ohio, but published detailed descriptions did not appear until 1950.

Most cases of cat scratch disease follow scratches or bites by domestic cats. But other sources have also been recognized, including thorns, cat urine, and bone spicules. No definite clinical disease in the offending animals has been discovered.

Lymphadenopathy is the most characteristic lesion of cat scratch disease. Usually the nodes draining the area of the primary lesion are involved, but extension to other parts of the body may also occur. Thus the axillary and epitrochlear nodes are most commonly involved in scratches or bites on the hand and forearm, the inguinal nodes with lower limb

lesions, and submandibular, suprascapular and cervical nodes following scratches about the face, neck, and chest.

In addition to the typical picture of regional lymphadenopathy, syndromes involving bone, central nervous system, eyes, and the spleen have been observed.

Geographically, the disease is widespread, having been reported in Europe, Great Britain, North and South America, and Asia. Undoubtedly many cases occur that are as yet unrecognized.

The causal agent has never been identified. It has been presumed that an agent similar to those of the psittacosis-lymphogranuloma venereum group is responsible, but recent information does not tend to confirm this presumption.

Extensive microbiological and pathological studies have been done and, although no proven etiological agent has been discovered, characteristic histological lesions have been described. There is no specific skin test that is quite accurate in diagnosis.

There are no public health methods presently applied for the control or treatment of this disease. As the association of man with domestic pets continues, increasing numbers of clinical cases are likely.

The Pan American Zoonoses Center

BENJAMIN D. BLOOD,
*Pan American Sanitary Bureau,
Buenos Aires, Argentina.*

The Pan American Zoonoses Center is an international institution dedicated to promoting and strengthening activities against the zoonoses in the Americas. Its services are available to health departments, agriculture departments, educational institutions, and other agencies interested in the zoonoses: those diseases naturally transmitted between animals and man.

The center, which has its central site in Azul, Province of Buenos Aires, Argentina, was established in August 1957. The Pan American Sanitary Bureau is the sponsoring international organization, although provisions have been made for other international agencies to

the large establishment. It seems in many instances that methods of control and measures for their enforcement have not kept pace with advances in food processing. More rigid control of products becomes even more important and practical when it is remembered that salmonellae may survive temperatures to which food products are sometimes subjected in cooking. Since it is possible to pasteurize certain food products effectively or to destroy salmonellae in them through a combination of acidification and mild heating, it would not seem unreasonable to adopt and enforce bacteriological standards for such products. New processes of food preparation and storage require new and improved procedures and practices to deal with them.

All of the writers who have given serious thought to the control of salmonellosis agree that effective control can result only through the cooperation of governmental agencies dealing with health, agriculture, and food. Further, it is agreed that salmonellosis should be a reportable disease of both man and animals, and that effective reporting and control measures should be enforced.

Through cooperation of physicians, health officers, veterinarians, and sanitarians with the proper governmental agencies, and through education of the public in the fundamental sanitary aspects of the preparation and preservation of foods, control of the infections may be expedited.

Newcastle Disease

ROBERT P. HANSON, *University of Wisconsin, Madison*, and C. A. BRANDLY, *University of Illinois, Urbana*.

Newcastle disease is a minor occupational disease limited chiefly to persons working with chickens and eggs and to those concerned with control of the disease. The population at risk is rather sizable since poultry is raised on approximately 3,418,000 farms in the United States.

In all known instances, infection of man has been limited to the initial case, the transmission

being from bird to man and never from man to man. Acute conjunctivitis is the usual manifestation, although systemic disease has been reported. Initial diagnosis of Newcastle disease in man is dependent mainly upon isolation of the virus, for the serology is complicated by certain problems of interpretation.

The importance of Newcastle disease lies in the resulting higher-priced poultry products and a reduction in their quality. The disease may kill, but more often it affects the poultry by interrupting growth and egg production, and it increases the percent of birds and eggs rejected for abnormalities.

While vaccination has permitted profitable production of poultry, it has not eliminated the virus in any part of the Nation, and it has not reduced the hazard of human infection. An organized control and eradication program is lacking, and without one the virus is afforded infinite opportunity to give rise to a mutant capable of maintaining itself in the human population.

Pulmonary Adenomatosis in Sheep

FRANCISCO DURAN-REYNALS and KEEN A. RAFFERTY, *Yale University School of Medicine, New Haven, Conn.*, E. JUNGHERR and D. HELBOLDT, *University of Connecticut, Storrs, Conn.*, and A. CUBA-CAPARO, *University of San Marcos, Lima, Peru*.

Workers in various parts of the world have described several invariably fatal pulmonary diseases of sheep that can probably be grouped together into a complex of related entities.

Histologically, these diseases can be arranged in a spectrum, with pure infiltrative pneumonia or pulmonary lymphomatosis at one end, and metastasizing adenocarcinoma at the other. All degrees and combinations of inflammatory neoplastic disease occur between the two extremes, some forms being histologically indistinguishable from human pulmonary adenoma.

Representatives of all forms are naturally contagious, including the metastasizing adenocarcinoma of Peru, and there is considerable evidence that all forms in sheep are naturally transmissible. Experiments now under way with an infiltrative form occurring in Montana

tendency, renal, hepatic, and vascular failure, and a high fatality rate. Symptoms persist from 1 to 3 weeks. Leptospiremia and leptospiruria occur at various stages and antibodies are demonstrable in convalescence.

The currently recognized human American species of *Leptospira* are *icterohemorrhagiae*, *canicola*, *pomona*, *bataviae*, and *autumnalis*.

Milder forms of illness result usually from infection by leptospirae other than *L. icterohemorrhagiae* and *L. bataviae*. Over 200 patients with leptospirosis contracted in a tropical environment had fevers enduring from 4 to 20 days, with an average of 8 days. Studies conducted in Malaya from 1954 to 1955 revealed leptospiral infections to be a significant cause of short-term pyrexia. Only two fatalities occurred among these patients and few presented overt clinical evidence of hepatic, renal, or cardiovascular insufficiency.

Clinical features may resemble aseptic meningitis. A leptospiral etiology should be considered in any illness characterized by fever, myalgia, nausea or vomiting, conjunctival injection, proteinuria and neutrophilia.

Rheumatoid Arthritis in Man and Arthritis in Swine

DENNIS SIKES,

University of Georgia, Athens.

Arthritis in swine is prevalent under farm conditions. In some cases, an infectious agent can be isolated; in others, none can be found. Pyogenic bacterial infections produce enlarged, soft joints distended with pus. This purulent type of infection occurs most frequently at the time of birth, probably through the umbilicus.

In *Erysipelothrix rhusiopathiae* infections, the organism may disappear from the joints while the arthritis persists. In such cases many macroscopic and microscopic pathological changes similar to rheumatoid arthritis in man are present.

In acute arthritis there is synovitis, characterized by vascular engorgement, and edema of the synovial tissues. The effusion is turbid or serosanguineous and mucinous. The synovial

villi show evidences of beginning proliferation and beginning lymphocytic infiltration. Later, greater proliferation and less edema are observed. Proliferation of the mesothelial cells covering the hypertrophied synovial villi is present. The villi contain young, highly vascular connective tissue, plasma cells, and lymphocytes. A striking feature is the accumulation of dense collections of lymphoid cells resembling germinal centers of lymphoid tissue.

In advanced chronic arthritis with pannus formation of subchondral origin, fibrosis in the adjacent narrow spaces, increased vascularity, and collections of lymphocytes occur. Pannus formation over the articular cartilage with or without fibrous ankylosis, narrowing of the joint spaces with rarefaction of the adjacent bones, and greatly thickened capsules are evident.

A comparison of arthritis of swine and rheumatoid arthritis of man shows some similarities. In both diseases, the changes are essentially proliferative and nonsuppurative and have a tendency toward granulomatous proliferation in the synovial membrane. Pannus formation and focal accumulations of lymphocytes are observed. Destruction of cartilage at the site of pannus attachment and subchondral cellular reactions appear similar. Rarefaction of the bone as revealed by radiography and intra-articular fibrous adhesions are common to both diseases.

Listeriosis: A Public Health Problem

JOHN F. WINN, WILLIAM B. CHERRY, and
ELIZABETH O. KING, *Communicable
Disease Center, Public Health Service,
Atlanta, Ga.*

Listeriosis is a little known, infrequently recognized, but widespread bacterial disease of man and other warm-blooded creatures. The causative agent, *Listeria monocytogenes*, has been recovered from man, mammals, and birds in a number of countries all over the world, and in 22 of the 48 States.

Morphologically, the organism is a gram positive, non-acid-fast, non-spore-forming rod.

Main building of the Pan American Zoonoses Center in Azul, Province of Buenos Aires, Argentina. The only international institution of its kind, the center is primarily devoted to research on diseases communicated from animals to man. The center was

established in August 1957 as a result of a special agreement the previous year between the government of Argentina and the Pan American Sanitary Bureau, Regional Office for the Americas of the World Health Organization.

join forces with the Bureau. Provisions have also been made for direct support of the center through contributions from any country.

The center is designed to educate and train professional and paraprofessional personnel in techniques and methods to combat the zoonoses. It will also (a) conduct research to improve diagnosis, epizootiological-epidemiological knowledge, and control procedures; (b) promote, aid, and coordinate such research in government and private institutions; (c) work toward the standardization of diagnostic methods for making and testing vaccines, serums, antigens, and other biological products; (d) prepare and disseminate information on the zoonotic diseases; and (e) develop field demonstration activities in accordance with the needs of participating countries.

Promoting and strengthening governmental activities against the zoonoses in the Americas is the principal function of the center. But this objective can be reached only insofar as there are sound technical activities and services

in each country dedicated to research, control, and eradication of diseases common to man and animals.

While there are over 80 zoonoses, the center will give priority to those of major importance in the Americas: rabies, brucellosis, hydatidosis, tuberculosis, encephalitis, salmonellosis, psittacosis, and anthrax.

Leptospirosis in Man

THEODORE E. WOODWARD and JOE L. STOCKARD,
University of Maryland, Baltimore.

Human leptospiral infections comprise a multiplicity of separate syndromes whose clinical features vary from mild grippe-like illnesses to those simulating fulminant hepatitis or "aseptic meningitis." The classical disease, described by Weil in 1886, is caused by *Leptospira icterohemorrhagiae* and is recognized clinically by the development of fever, icterus, conjunctival injection, myalgia, hemorrhagic

infections, tularemia, and the viral encephalitis, to name but a few, dominate any such list? They certainly possess some of the characteristics considered in a good biological warfare agent such as high infectivity and stability.

Second is the field of antianimal agents. The widespread outbreak of such foreign animal diseases as foot-and-mouth disease, African swine fever, rinderpest, and Newcastle disease in our domestic animals, to mention but a few, could result in a drastic, if not complete, reduction of available food supplies. This would be particularly true if coupled with a successful destruction of crops.

Third, and perhaps the only silver lining in the defense picture, is the far-reaching benefits human health has received as a result of research in animal disease. Advances in epidemiology, bacteriology, and immunology, for example, are already actively utilized in advancing the health of the Nation.

Orphan Viruses of Man and Animal

G. D. HSIUNG and JOSEPH L. MELNICK,
*Yale University School of Medicine,
New Haven, Conn.*

Refinement of tissue culture methods and expansion of their use into the field of virology has brought into focus large numbers of viruses heretofore unrecognized. It is well known that families of viruses, such as herpes and pox, exist in different species, and now it appears that there are also enteric viruses for a number of different animal species. These are enteric cytopathogenic orphan viruses for humans (ECHO), monkeys (ECMO), bovines (ECBO), and swine (ECSO).

ECHO viruses, of which there are at least 19 antigenic types, have been isolated from normal children and from patients with aseptic meningitis syndrome. Because the human diseases to which they belonged were unknown, and because they failed to produce illness in laboratory animals, including infant mice, they were originally called "orphan viruses."

The difference in colony (plaque) morphology and in host cell susceptibility have sug-

gested that the ECHO viruses may be divided into two groups. The selection of the proper serum for antigenic identification has been made easier by such a preliminary grouping.

ECMO viruses are included among the simian viruses of Hull and his colleagues. They may be divided into three groups according to their plaque morphology and patas cell susceptibility. Positive CF reactions were obtained between strains of one group of ECMO viruses and human serum known to contain adenovirus antibodies.

ECBO viruses isolated by Kumin and by Klein grow readily in bovine kidney cultures; some have been found to propagate in monkey kidney cells, but not in HeLa cultures. Those tested have proved to be antigenically distinct from human viruses.

ECSO viruses were isolated from newborn pigs by Moscovici in Italy. The virus grew rapidly in monkey and swine kidney cells, but HeLa cells failed to respond.

In view of this study it is believed that colony morphology and cell susceptibility, classical criteria for classification of enteric bacteria, are of similar value for identification of orphan viruses isolated from man and animal.

Viral Hepatitis in Animals and Man

MORRIS POLLARD,
*University of Texas Medical Branch,
Galveston, Tex.*

Viral hepatitis has been described in man and other animals, including dogs, pigs, mice, and ducks. Such viral agents appear to be characteristically narrow in their host susceptibility. Since for laboratory investigations the viral hepatitis agents of man are not transmissible to other animal species and are difficult to evaluate in tissue culture, mouse hepatitis virus has been studied as a possible prototype of the human equivalent.

Mouse hepatitis virus in embryonated chicken eggs induces changes resembling the effect of acute serum from viral hepatitis of man. Inoculums containing virus induce an

There is a tendency for the organisms to arrange themselves into "V's" or into a palisade formation when the smear is made from solid media. The bacteria stain evenly and are 0.5 to 0.6 by 1.0 to 2.0 microns in size. Short, but sometimes long, threadlike chains may be observed in the rough phase of growth. Capsules are not demonstrable. Motility can be demonstrated in 6-hour glucose broth cultures, but it is more pronounced at 25° C. after 24 hours incubation. The peritrichously flagellated organisms have a characteristic tumbling motion.

Listeria frequently fails to grow when cultured from fresh tissues, but it has been found that refrigeration of the original necropsy specimens and periodic subculturing will increase the number of isolations obtained. There are four serotypes of *Listeria*, and among these are several biotypes. All serotypes and biotypes can and do attack man, poultry, and mammals.

The specificity of agglutinating titers is open to question since some serums spontaneously agglutinate antigen, and *Listeria* shares antigens with other bacteria. This being the case, agglutination titers should be interpreted with caution and preferably compared with the complement fixation test.

Listeriosis in sheep and cattle usually is readily recognized, and the etiological agent is frequently recovered without difficulty. The main clinical manifestations caused by *Listeria* in ruminants, swine, and man are meningoencephalitis, septicemia, and abortion. In animal infections, there is a definite seasonal distribution. The greatest number of animal cases occur during the winter and spring months. This does not appear to be true of human infections. Sex and age distribution in both animals and man appear to show little differences in the incidence of infection, but the younger the creature, the more unfavorable the prognosis.

Therapeutic agents have been evaluated in animals and man, and the tetracycline group have been found to be the most effective; penicillin and sulfonamides in combination proved almost as effective. The in vitro sensitivity gives some indication of the agent of choice. Vaccination of animals has been attempted, but

the trials have not been wholly successful. Further tests, however, should be made.

Since 1950 there have been 83 human cases in the United States verified by the Communicable Disease Center's laboratories, and since 1954 there have been 2,106 animal cases (representing herd and individual cases). We may conclude, therefore, that listeriosis is a public health problem, especially since we do not know the frequency of occurrence nor do we understand the epidemiology of the disease. We do know that it is widespread, that it occurs in humans and animals, and that it is frequently fatal. We also know that the premature infant and the aborted fetus may be due to congenitally acquired *Listeria* which does not manifest itself in an overt illness of the mother, that all ages and both sexes are susceptible, and that animal contact is not necessarily a factor in the epidemiology of listeriosis.

Animal Disease and Biological Warfare

LT. COL. JACK H. HEMPHY,
*Office of the Surgeon General,
U. S. Air Force, Washington, D. C.*

Biological warfare may be defined as the intentional use of living micro-organisms or their toxic products for the purpose of reducing the military effectiveness of man. This use includes damage to or destruction of his food sources.

Do we have reason to concern ourselves with defense against such warfare? History answers in the affirmative. From the earliest to most modern times it tells us that nations at war will and have used every known weapon system that offers them a possibility of achieving victory.

What is the relationship of animal disease to defense against biological warfare? A brief exploration of three major facets of a biological warfare defense program reveals a close and vital relationship.

First is the field of potential antihuman agents. Would not the zoonoses, animal diseases transmissible to man, such as mycotic

11.5 to 1.8 percent of the animals checked. A similar reduction has occurred in the number of herds carrying the infection. For fiscal year 1935, infected animals were found in 36.2 percent of the blood-tested herds. As of June 30, 1957, this figure was 10.5 percent.

In October 1954 the bovine brucellosis eradication campaign was accelerated by additional Federal funds, and progress during the past 3 years exceeded that reported for any similar period since the program's inception. At present approximately half of all cattle in the United States are under supervision for the control and eradication of brucellosis.

The initial goal of the eradication campaign is to establish and maintain certified brucellosis-free areas. This designation signifies that the infection appears in no more than 1 percent of the animals and 5 percent of the herds. At the end of fiscal year 1957, 735 counties and 7 entire States were certified. Another 712 counties were actively working on programs leading to certification. This means that nearly 50 percent of all counties in the United States, Puerto Rico, and the Virgin Islands are either certified or are rapidly approaching that status. It is estimated that by June 30, 1958, a total of 16 States will be certified.

If the present level of field operations can be maintained, there is every reason to believe that the incidence of bovine brucellosis throughout the United States can be reduced to 1 percent or less by 1960.

Brucellosis in Man

NORMAN B. McCULLOUGH,
*National Institutes of Health,
Public Health Service,
Bethesda, Md.*

With more widespread pasteurization of milk and other dairy products, brucellosis in the United States has become almost entirely an occupational disease affecting persons intimately exposed to infected animals or their tissues. In the last 10 years the number of cases reported annually has dropped considerably; nevertheless, if one excepts salmonellosis deriving from animal sources, brucellosis in the

United States still has a higher reported incidence than any other disease of animals transmitted to man.

While great strides have been made in the last few years in the control of bovine brucellosis, and the incidence of the infection in cattle has been greatly reduced, the decrease in notified incidence in man cannot be clearly related to the success of the control program. Swine continue to be an important source of infection for man.

Despite the decrease in the number of reported cases, the problem of establishing the diagnosis of the disease in man remains an important one. Isolation of the organism from the patient is the only proof of diagnosis. A significant titer in the standard seroagglutination test, or a rising titer, provides presumptive confirmation of a clinical diagnosis. In chronic brucellosis a fluctuating titer is suggestive of active disease. The widespread and often indiscriminate use of the broad-spectrum antibiotics makes cultural proof more difficult, and greater dependence must be placed upon the agglutination test. The skin test has no value as a diagnostic aid.

The current therapy of choice consists of a combination of dihydrostreptomycin and tetracycline, with or without the addition of sulfadiazine or triple sulfonamide. As all presently available drugs primarily suppress the infection, treatment must be continued for a period of time sufficient to allow the body to dispose of the infection. Bed rest is essential. Local lesions may require longer medical treatment or definitive surgical treatment.

Vector Relationships of Arthropod-borne Encephalitides in North America

ROY W. CHAMBERLAIN,
*Communicable Disease Center,
Public Health Service,
Montgomery, Ala.*

Although much remains to be learned about the ecology of the arthropod-borne encephalitides in North America, past and recent studies

increase in the number of lymphoid cells in the allantoic fluid; in inoculums containing heat-inactivated virus, the cellular response is absent. Serial passage of inoculated egg material has failed to show reproduction of murine and human hepatitis viruses in avian tissue. Four logs of mouse-infective virus are required to elicit the cytological response in embryonated eggs, thus indicating that the egg is very much less sensitive to virus than the natural host.

Mouse hepatitis virus does not propagate in "L" strain of mouse fibroblast in tissue cultures, and human hepatitis virus has induced no detectable cytopathogenic effect in cultures of human tissues.

A soluble complement-fixing antigen has been extracted from liver emulsions of mice infected with hepatitis. The antigen can withstand desiccation, heat, extraction with ether, and freezing; it does not sediment at 120,000 gravities for 2 hours. "Normal" liver does not contain this antigen. An antigenic relationship of mouse hepatitis virus to human disease has not been demonstrated.

Neutralizers of Human Viruses in Animal Serums

MORTON KLEIN,
Temple University, Philadelphia, Pa.

Certain domestic animals, particularly cows, have neutralizing substances in their serums against certain human viruses such as polioviruses, coxsackie, and adenoviruses. These antibodies occur in the absence of any known infection with the agents and raise the question of their interpretation. Are they true antibodies?

A study of the neutralizing substance against polioviruses in cow serums revealed the following characteristics: It is a globulin, heat stable at 60° C. for 30 minutes and highly specific. Some serums have no neutralizing substances; others have neutralizing substances to types 1, 2, and 3 polioviruses or combinations of these. There is evidence of passive transfer: newborn calves commonly have neutralizing substances that disappear at 4 to 5 months and gradually

reappear over a period of time in the traditional fashion of antibodies. Titers are variable and may be quite high: dilutions greater than 1:128 neutralize 100 TCD.

A review of the literature indicates that although certain nonspecific inhibitors may have one or more of these properties, no substance other than specific antibody is known to have all of these properties.

Even when one has determined that he is dealing with a true antibody, a more difficult question remains. What is the nature of the antigenic stimulus for the antibody? Cross reactions between viruses of which there are already many examples (canine distemper and measles, vaccinia and variola, swine influenza and influenza, psittacosis and lymphogranuloma venereum) make final interpretation or origin impossible.

The problem is particularly difficult in surveys of animal serums when one does not have the orienting information of a known reservoir, or an epidemic situation with a characteristic clinical picture and paired serums to observe a fourfold rise in titer.

Although one may conclude that the neutralizing substances in bovine serums are true antibodies that react with polioviruses, coxsackie, and adenoviruses, the final interpretation as to the origin of these antibodies requires the isolation of a specific agent that can explain the antibody pattern. In the absence of such isolations, the origin must remain an object of closely reasoned but inconclusive speculation.

Brucellosis in Livestock

C. K. MINGLE,
*U. S. Department of Agriculture,
Washington, D. C.*

Brucellosis in livestock continues to be an important economic burden and public health threat in many sections of the United States.

Since 1934 a cooperative State-Federal program for the control and eradication of bovine brucellosis has been in operation. During that time the number of reactors disclosed through blood agglutination testing has declined from

exists in the central and east central States, where *C. tarsalis* is not abundant. There *Culex pipiens* or *Culex quinquefasciatus* are apparently the important epidemic vectors and a high proportion of the cases are urban or suburban.

The mechanics of an urban epidemic appear clear. Infected wild birds probably introduce the virus to high populations of suburban and urban *C. pipiens* or *C. quinquefasciatus*, which rapidly spread it to city-dwelling birds and chickens. These, in turn, serve as a ready source of infection for additional numbers of the mosquitoes. A consequence of the resultant bird epizootic is exposure of a large segment of the human population to infection by mosquito bite. The vectors responsible for the initial infection of the wild birds are unknown, but widespread sylvan mosquitoes may be involved.

Control measures through vector abatement are often economically impractical. Only urban SLE gives immediate promise of relatively inexpensive control. It is obvious, therefore, that continued investigations on the ecology of encephalitis are necessary.

Changing Picture of Murine Typhus

HARRY D. PRATT, *Communicable Disease Center,
Public Health Service, Atlanta, Ga.*

The changing picture of murine typhus in the United States can be shown by comparing

two 4-year periods, 1941-44 and 1953-56. In the first period the number of cases of murine typhus increased to a peak of 5,401 in 1944, while in the latter period the number of cases decreased to 98 in 1956. This is the first year since 1924 that less than 100 cases of murine typhus have been officially reported to the Public Health Service.

Treatment in the first period was largely symptomatic; today, broad spectrum antibiotics, such as chloromycetin, aureomycin, and terramycin, give quick and effective cures. The use of these new drugs, however, probably obscures the true incidence of the disease. They mask all types of rickettsia infection, making diagnosis with laboratory confirmation difficult or rare.

Prevention of murine typhus during the first 4-year period was based on controlling rat fleas, rat trapping, rat poisoning (using relatively ineffective rodenticides such as red squill), rat proofing, and sanitation. Today, in addition to these methods, there are powerful insecticides which control infected rat fleas for weeks or months. Many new rodenticides have been developed, particularly the anticoagulants, which control rodents effectively and thus limit the flea population.

Improved sanitation programs in cities throughout the United States, and increasing reliance of private industry on commercial pest control services, have probably had a long-term influence on the steady decrease of murine typhus.

John W. Cronin, 1905-1958

Dr. John W. Cronin, Assistant Surgeon General of the Public Health Service, and chief of its Bureau of Medical Services since November 1956, died of a heart attack March 26, 1958.

Born June 15, 1905, in Springfield, Ohio, he began his career with the Public Health Service in 1932. As chief of the Hill-Burton program from 1949 to 1956, he is credited with rallying State support for the construction and enlargement of hospitals, nursing homes, and clinics throughout the United States.

Dr. Cronin was a graduate of Miami University, Oxford, Ohio, and of the Cincinnati University College of Medicine.

have provided a considerable knowledge of these diseases. The most probable hosts and vectors have been revealed.

Field investigations have shown fresh water swamps to be the foci of eastern equine encephalitis (EEE) infection. Wild birds captured in swamps have frequently been found infected, and numerous virus isolations have been made from *Culiseta melanura*, a swamp-inhabiting mosquito which feeds principally upon birds.

Because of its restricted habitat and feeding preferences, *C. melanura* is probably unimportant in the direct epidemic spread of EEE to horses and man. Although it appears to play the important role of maintaining the virus in its endemic foci, the spread of the disease outside of these foci is most likely dependent upon other mosquito species which feed commonly upon horses and man.

Certain conditions appear necessary to permit an epizootic in horses (and an epidemic in man) to occur. Bird infection within the swamp foci would need to be at high level, furnishing a relatively great source of virus for mosquito infection. This condition would depend upon an adequate population of *C. melanura* (and perhaps other susceptible bird-feeding, swamp-inhabiting species), and a low immunity rate in the bird population. The latter would, in turn, depend upon a light infection rate the previous year. With a large number of birds infected, inevitably some of them fan out into adjacent nonswamp areas and serve as sources of infection for other mosquito species which will feed upon horses and man. The scattered distribution of the infected birds, together with a lack of strong bird-feeding proclivity on the part of the mosquitoes, results in only a very low mosquito infection rate; this must be compensated for by large mosquito numbers. If, in addition to all this, there is also a low immunity rate in the horse population, conditions are proper for an epizootic. Once the epizootic is under way, some transmission from horse to horse by mosquitoes and biting flies without the intervention of birds is probably also possible.

The ecology of western equine encephalitis (WEE) has undergone intensive investigation over many years. Serologic and virus isolation

studies in wild birds have firmly established their role as the most important hosts, and hundreds of isolations of the virus from *Culex tarsalis* attest to the close association of this mosquito species with natural sources of infection. Since it is widespread in distribution, occurs in large numbers, feeds freely upon man and horses as well as birds, is exceptionally susceptible to infection, and transmits with high efficiency, it fulfills requirements for both an endemic and epidemic vector. It undoubtedly is responsible for the bulk of the WEE transmission to birds, horses, and man throughout its range in the western part of the United States. *Aedes* mosquitoes appear to play only a minor role in epidemic transmission.

Until a few years ago the distribution of WEE was believed to be limited to that of *C. tarsalis*. It is now known that it does occur in mosquitoes and birds in the East in the absence of *C. tarsalis*, however, but does not cause disease in man and is only rarely seen clinically in horses. In the East the enzootic status of WEE appears to be similar to that of EEE, with *C. melanura* in fresh-water swamps playing the role of the principal enzootic vector. The absence of a highly efficient epidemic vector, such as *C. tarsalis*, is probably the main factor in keeping the virus within discrete enzootic foci. Also, laboratory studies have shown that animals immune to EEE respond to WEE infections with significantly lower viremias. This may be a contributing deterrent to the epidemic spread of WEE in areas where a high proportion of birds and horses possess EEE antibody.

St. Louis encephalitis (SLE), like EEE and WEE, is primarily an infection of birds transmitted by mosquitoes, with man an unfortunate, accidental host. The virus of SLE differs from those of EEE and WEE, however, in having a reversed mosquito susceptibility range. It readily infects all species of *Culex* mosquitoes which have been tested, whereas EEE and WEE viruses find most *Culex* species (except *C. tarsalis*) almost totally refractory.

In the far west, *C. tarsalis* is the main vector of SLE and, as would be expected from the breeding habits of this mosquito, most of the human cases are rural. A different situation

EJECTION

AUTOMOBILE FATALITIES

BORIS TOURIN, B.A.

PRIOR to the advent of studies of injuries sustained in automobile crashes, the belief was prevalent that being "thrown clear" of the car during an accident would generally save one's life. As the Automotive Crash Injury Research project of Cornell University Medical College accumulated case histories from the reports of trained police and highway patrol investigators, however, it became clear that this supposition was contrary to the evidence.

The present study uses data from these reports to answer two initial questions: Is the risk of fatal injury greater for those ejected from automobiles in an accident than for those who remain inside? What fatality would be expected for those ejected had they remained inside the cars?

Answers to these questions are applied to data on national fatality figures in order to answer a third question, which is the principal objective

Mr. Tourin is chief of the technical section of Automotive Crash Injury Research, a division of the department of public health and preventive medicine, Cornell University Medical College, New York City. This investigation was supported in part by the Commission on Accidental Trauma of the Armed Forces Epidemiological Board (with funds provided by the Surgeon General, Department of the Army), the National Institutes of Health, Public Health Service, the Ford Motor Co., and the Chrysler Corp.

of this study: If ejection increases the risk of fatality, what is the estimated number of lives that could be saved annually by preventing ejection in injury-producing accidents?

The present study is an extension of an earlier one in which it was observed that ejection from an automobile under crash impact conditions was associated with a double risk of moderate through fatal injuries (1). Both the previous and present studies represent portions of the large-scale investigation of injuries in automobile crashes conducted at Cornell University Medical College. The general plan and organization of this investigation have been described in previous reports (1-4).

Materials

Detailed accident-injury reports, containing comprehensive information on 3,261 passenger automobiles and their 7,337 occupants, were collected and analyzed and subsequently coded and transferred to punchcards.

All of these accidents had resulted in injury of some kind to at least one of the occupants involved. The accidents ranged in severity from minor to extreme, and the injuries ranged in degree from trivial to fatal.

All common makes and models of American automobiles manufactured prior to 1956 and operated during the sampling period (beginning of 1953 through May 1956) were repre-

Home Accident Prevention Text

PHS Publication No. 564. 1957. 24 pages. 15 cents.

The Home Accident Prevention Text provides both guidance and reference suggestions for all categories of local public health workers whose cooperation will be required in a local home accident prevention program. Following an introductory survey of environmental, physical, mental, and emotional factors in home accidents, the booklet analyzes the roles of the health officer, public health nurse, sanitarian, and other health personnel. The important contribution of the private physician to the success of local programs and the value of cooperation with other agencies in the community are stressed.

One Way to Develop Local Home Accident Activities

PHS Publication No. 566. 1957. 10 pages. 35 cents.

Designed to aid local health departments, *One Way to Develop Local Home Accident Activities* outlines a "learning by doing method." It presents a four-point program: staff orientation, local resources, the local problem, and suggested activities.

Sources of Morbidity Data, Listing Number 5, 1957

PHS Publication No. 565. 1957. 81 pages.

This fifth listing of projects in the files of the Clearinghouse on Current Morbidity Statistics Projects describes 105 projects not previously reported. The projects are grouped according to the major type or types of disease, injury, or impairment with which they deal.

There are three indexes: the projects by type of data collection, the organizations and institutions responsible for the research, and the principal investigators. Also included is a section of supplementary notes on projects in progress when their descriptions were received by the clearinghouse for inclusion in previous listings.

Since the listings of the clearinghouse are published primarily for the use of actual and potential contributors, the number of bound copies for other distribution is limited. Tear sheets of the description of each study are available, however, to research workers or persons planning public health programs.

Survey of Compounds Which Have Been Tested for Carcinogenic Activity, Supplement 1

PHS Publication No. 149. Supplement 1. 1957. By Philippe Shubik and Jonathan L. Hartwell. 388 pages. \$3.50.

This supplement surveys the literature from 1938 through 1943 on compounds that have been tested for cancer-producing properties in experimental animals. Having the same format as its predecessor, it combines in tabular form experimental data on nearly 1,000 compounds, of which about one-fifth are cancer-producing in animals.

The compounds are arranged alphabetically in classes, and the data cited include reference, species and number of animals, route of administration, number and type of tumors, and duration of experiment. A cumulative compound index, one of several indexes, includes the listings in both PHS Publication No. 149 and the supplement.

Because of the growing importance of chemicals in food, drugs, and cosmetics, and the increasing aware-

ness of the possible long-range effects of these and other materials such as the products of combustion of tobacco and gasoline on the human organism, the book should be useful to anyone interested in environmental cancer as well as cancer investigators.

Research Grants and Awards, National Institutes of Health, 1957

PHS Publication No. 571. 1957. 177 pages. 45 cents.

Health research facilities grants, research fellowships, and research grants awarded by the National Institutes of Health during fiscal year 1957 are listed separately by State and institution.

Toward a Healthier World—Your Career in Sanitary Engineering

PHS Publication No. 579. 1958. 16 pages; illustrated. 25 cents.

This is the first career guidance pamphlet to describe sanitary engineering. Designed especially for high school students, it covers past achievements of sanitary engineers, their present and future work, the need for such engineers, salary, possible employers, and educational requirements.

This section carries announcements of new publications prepared by the Public Health Service and of selected publications prepared by other Federal agencies.

Unless otherwise indicated, publications for which prices are quoted are for sale by the Superintendent of Documents, U. S. Government Printing Office, Washington 25, D. C. Orders should be accompanied by cash, check, or money order and should fully identify the publication. Public Health Service publications which do not carry price quotations, as well as single sample copies of those for which prices are shown, can be obtained without charge from the Public Inquiries Branch, Office of Information, Public Health Service, Washington 25, D. C.

The Public Health Service does not supply publications other than its own.

been avoided in the sample if ejection had been controlled. The proportion thus obtained, when applied to national fatality figures, provides an estimate of the number of lives that could have been saved by preventing ejection.

Fatality Risks in Ejection

Among the 7,337 occupants of passenger automobiles involved in any type of injury-producing accident, 13.6 percent were completely ejected, and 81.6 percent remained inside the car. Information on the remaining 4.8 percent of the occupants was doubtful, and these were eliminated from the study.

In table 1, persons completely ejected are compared with persons who definitely remained inside the car, and the proportion of fatally injured persons in the two groups is shown, thus providing an answer to the question: Is the risk of fatal injury greater for ejected persons than for those who remain inside the car?

There were 9.6 percent fewer fatalities among those not ejected than among those ejected ($P<.001$). Further, the risk of fatality among the ejected was demonstrated to have been nearly five times as great as that among those not ejected: 12.1 percent for those ejected versus 2.5 percent for those not ejected. These data clearly suggest that the number of fatalities in automobile accidents would be reduced by minimizing the occurrence of ejection.

The material which follows deals with the methodology and rationale employed in predicting the number of lives that would have been saved in the sample if those ejected had not been ejected. This methodology must, of

course, take into account the fact that a certain number of persons, even if they had remained inside the car, would nevertheless have been exposed to some risk of fatal injury; that is, at least the 2.5 percent risk experienced by those not ejected. Thus it must by no means be assumed that the 5 to 1 ratio seen in table 1 implies an 80 percent reduction in the total number of fatalities if ejection is eliminated. Furthermore, it also cannot be assumed that the occurrence of fatality is related exclusively to the occurrence of ejection or nonejection. Other accident-injury factors must be taken into account.

Accident Severity, Seats, and Fatality

As has been indicated in table 1, the risk of fatality was greatly influenced by the occurrence of ejection. In addition, the influence of at least two other major variables affecting both the frequency of ejection and the risk of fatality have been definitely established in previous research (6, 7) and have to be taken into account. These factors are accident severity and seated position, both of which are believed to have sufficient bearing on the subject of this investigation to warrant particular attention.

Figure 1 illustrates the frequency of fatality in progressive categories of accident severity. Statistical analysis of the data, revealed a significant increase ($P<.001$) in risk of fatality as accident severity increased. Figure 2 illustrates the frequency of fatality among car occupants according to seated position occupied and shows that the risk of fatality was significantly different ($P<.001$) for occupants of different positions. In these two figures, in order to eliminate over-emphasizing driver injury, data on drivers alone and drivers with passengers are presented separately.

The effect of these same factors on the frequency of ejection is illustrated in figures 3 and 4. Figure 3 illustrates that as accident severity progressively increased, the frequency of ejection significantly increased ($P<.001$). Figure 4 illustrates the varying and significantly different ($P<.001$) frequencies of ejection depending on seated position. In particular, the rear seat area produced much lower risk of ejection than the front seat area. This was due

Table 1. Risks of fatal injury for those ejected and those not ejected

¹ Data on 350 of the 7,337 occupants studied have been omitted since details on ejection were not completely reported for these persons.

sented. Those manufactured after 1956 were excluded because many manufacturers improved their door locks in that year. Doors equipped with these new lock mechanisms have been demonstrated to open less frequently under crash impact conditions and to be associated with a decrease in the frequency of ejection (2).

The data were collected at the accident scene in 14 States and 1 city: Arizona, California, Colorado, Connecticut, Indiana, Maryland, Michigan, Minnesota, New York, North Carolina, Pennsylvania, Texas, Vermont, Virginia, and Minneapolis. The States provide the sample with rural accidents; the city, with urban accidents.

In each participating area, police or highway patrolmen in preselected geographic districts completed special report forms and submitted detailed photographs for each injury-producing accident. Examining physicians supplied precise medical information on each injured person. History, data sources, and general methods of the Automotive Crash Injury Research project have been previously outlined (3, 4).

These accidents are believed to be representative of typical crashes in which persons were injured (3).

Another source of material was the national motor vehicle fatality figures gathered by the National Office of Vital Statistics and reproduced by the statistics division of the National Safety Council (5). Such data are published annually in Accident Facts, where tabulations of accidental deaths and injuries from many sources are collected and classified under gross cause headings.

Methodology

Of all the passenger car occupants who were fatally injured, a distinction was made between those whose injuries resulted from contact with structures inside the car and those whose injuries were the direct consequence of complete ejection from the car, that is, the injuries were sustained outside the car. The 2 frequencies of fatal injury result in 2 different risks of fatality.

The following hypothesis was adopted to determine the expected risk of fatal injury for

Definitions

Accident severity: Total decelerative forces and overall structural damage produced by the accident, described in five grades: (1) minor; (2) moderate; (3) moderately severe; (4) severe; and (5) extremely severe and extreme. These terms do not describe the injury effects of the accident, but only the forces and structural damage conditions.

Complete ejection: Complete ejection through a door that has "popped open" as a result of impact against some portion of the car other than the door in question. Occupants defined as completely ejected must be outside the car before sustaining their principal injuries. Doors opened by direct impact to the doors themselves are not classified as open in studies concerned with ejection since occupants adjacent to these doors are quite likely to have been seriously injured prior to leaving the car.

Seated position: The position determined by where an occupant might sit: driver, right front, center rear, and so on.

Serious and critical injuries: Injuries which, because of their nature and severity, are potentially or actually dangerous to life.

those ejected had they remained inside the car, with the other circumstances remaining unchanged. It was postulated that had the occupants not been ejected, their risk of fatality would have been equivalent to the observed risk among persons who actually remained inside the car, in corresponding seats, and under the same force conditions. Pursuing this hypothesis, data were first arranged to show the observed risk of fatality for nonejected occupants in each category of seated position and accident severity. The expected number of fatalities among persons ejected from corresponding seated positions and in accidents of comparable severity could then be obtained by using the method of observation and expectancy.

Pursuing the original hypothesis further, the expected number of fatalities among occupants of all seats and in accidents of all severities, assuming that none had been ejected, was then compared with the observed number of fatalities to establish the proportion that would have

dent severity and seated position. For example, it is shown from the data in table 2 that among 578 nonejected right front seat occupants involved in moderately severe accidents, there were 6 fatalities, while among 115 ejected right front seat passengers in accidents of the same severity, there were 14 fatalities. To calculate the expected number of fatalities if ejection had not taken place, the data were arranged as a simple ratio: the expected number of fatalities among the ejected is to the total ejected as the observed number of fatalities among the nonejected is to the total nonejected. Expressed numerically, the ratio reads, $x : 115 :: 6 : 578$.

The expected number of fatalities among ejected persons was 1.19 (or about 1 person). But among the 115 ejected persons observed, there were actually 14 killed. Thus, in the given category of seated position and accident

Figure 3. Frequency of ejection according to accident severity.

Figure 4. Frequency of ejection from different seats.

severity, there were 13 more people killed than would have been expected if there had been no difference between risks of fatality for ejected and nonejected persons.

By totaling the observed and the expected fatalities in table 2 for each seated position and within ranges of severity, and then subtracting one from the other, the basis was provided for an estimate of the number of lives that could have been saved in the 3,261 accidents surveyed if ejection had not occurred. There were 121 observed fatalities and 53 expected fatalities among those ejected, a difference of 68, therefore, between the two.

The total number of fatalities observed among all occupants, whether ejected or not, was 268. Since 147 of these were among the nonejected group, they would not be affected by preventing ejection, and the expected number of fatalities here would be the same as the number observed. Therefore, preventing ejection could have reduced the number of fatalities by 68, leaving only 200 fatalities. (The 200 expected fatalities could also have been determined in this way: 147 observed among nonejected, plus 53 expected among ejected under the hypothesis.)

This reduction, expressed as the proportion 200/268 (74.6 percent), can be applied to the national fatality figures for passenger car occupants to obtain the estimated number of fatalities that would still occur throughout the Na-

largely to the fact that about half of the cars observed were two-door models; rear seat occupants were seldom ejected through the front doors.

Observed and Expected Risks

It has been clearly demonstrated that those ejected are much different from those not ejected with respect to risk of fatality and that, further, fatality risks will fluctuate considerably according to seated position and accident severity. The available data on these three factors affecting fatality risks were used to determine the answer to the question: What would have been the expectations in terms of fatality for the ejected had they remained inside the cars?

Strictly speaking, of course, it is impossible to determine what would have happened to any specific ejected person in a single, hypothetical situation if he had remained inside the car. However, given certain reasonable assumptions,

Figure 1. Frequency of fatality according to accident severity.

Figure 2. Frequency of fatality among all occupants of different seats.

it is possible to obtain an estimated (or predicted) number of fatalities representing the fatality risk of a category or group rather than of any individual in that category or group. Predictions under such conditions are described as expectations under a given hypothesis or, more briefly, expectations.

The volume of data on nonejected persons, 81.6 percent of the total number in this study, is sufficiently large so that the risks of fatal injury associated with given seated positions under given conditions of accident severity may be assumed to be representative for any single occupant who remains inside the car. A reasonable assumption is that the fatality risks to which a given ejected person would be exposed were he not ejected would be comparable to the fatality risk encountered by a group of nonejected occupants subjected to the same conditions of accident severity in a seated position corresponding to that from which the ejected person had been thrown. The fatality risks for nonejected persons according to accident severity and seated position can be taken directly from basic data. These observed fatality risks thus obtained provide a reasonable basis for calculating the expected number of fatalities that would have been encountered among ejected persons if they had stayed in their seats.

Calculations for Expectancies

Simple algebraic calculations, based on the rationale described above, yielded the expected number of fatalities in each category of acci-

tion even if ejection were controlled (3). Roughly 75 percent would still occur, which means a reduction of 25 percent.

National Fatalities

The National Office of Vital Statistics reported 39,628 deaths resulting from motor vehicle accidents of all descriptions in 1956. The annual figure has been fairly constant over the past 5 years (5). Since these tabulations included all persons fatally injured, under whatever circumstances, in accidents associated with motor vehicles of every description, they were not all applicable to the present study, which is concerned exclusively with fatal injury to passenger car occupants. Therefore, certain eliminations were needed in order to obtain the basic applicable figure accounted for by passenger car occupants among the national fatalities.

Among the fatalities eliminated were those incurred when motor vehicles collided with pedestrians or cyclists, since fatal injuries in these accidents were more likely to have been sustained by the latter than by the occupants of the motor vehicles. The nature of the National Safety Council's tabulations, subclassified under various categories, permitted the elimination of these fatalities without difficulty (5).

A further elimination was required with respect to fatalities among occupants of street cars, buses, trucks, and any other vehicles which could not be classified as passenger cars. Unfortunately, the national accident fatality tabulations did not distinguish between deaths among occupants of passenger cars and occupants of other motor vehicles. However, gross figures supplied by the National Safety Council (5), through data collection of the National Office of Vital Statistics (8), provided for the estimation that about 75 percent of the motor vehicles involved in fatal accidents were passenger cars. Most of the remaining 25 percent were trucks, which normally carry fewer passengers than automobiles. Therefore, it is perhaps overgenerous to presume that 25 percent of the fatalities in these accidents were sustained in vehicles other than passenger cars.

The results of all the above eliminations may be observed in table 3.

These eliminations result in a conservative estimate of 23,678 deaths annually among occupants of passenger cars involved in accidents. Roughly 87 percent of these deaths (20,528) occurred in rural accidents; the balance of 13 percent are accounted for by accidents in urban areas. In the following section it is estimated how many of these 23,678 lives might have been saved by preventing ejection. Since the estimate of passenger car occupant fatalities is very cautious, the predicted number of avoidable fatalities may represent an underestimation. In any case, it can safely be regarded as a minimum figure.

Application of Reduction Proportion

We have estimated that prevention of ejection could eliminate 25 percent of the fatalities observed in the study sample. Before applying this percentage to the adjusted estimate of 23,678 annual deaths among passenger car occupants throughout the Nation, certain differences between the sample data and the national tabulations had to be taken into account. For example, among those national fatalities pertinent to the problem (table 3), roughly 20,000 occurred in rural areas and about 3,000 in urban areas, with the ratio of rural to urban fatalities amounting to somewhat more than 6 to 1. In the sample studied the ratio of rural to urban fatalities was about 25 to 1.

Therefore, applied to national figures, the

Typical seat belt installation.

quency, nature, and severity of injuries associated with given causes. Reliable data of this kind can guide designers and engineers toward the elimination or delethalization of specific structures found to be potentially dangerous under crash conditions.

The relationship of automobile design to injury is nowhere more apparent than in the comparison of the frequency of fatality among ejected and nonejected occupants. If doors had not sprung open during impact, occupants could not have been ejected. Even if doors had failed to remain closed, by our definition of complete ejection, no occupant wearing a fully effective seat belt could have been thrown from the car. As statistical computation has indicated, 25 percent of all fatalities among passenger car occupants can be eliminated if ejection is completely prevented. Failure to control ejection implies the loss of more than 5,000 lives each year, and these deaths can no longer be accepted as unavoidable since the means of at least partial control exists.

If occupants can be retained inside the car in

future accidents, then the injury potential associated with structures within the passenger compartment can be reduced systematically with the cooperation of the automotive engineer. The use of properly designed and installed seat belts, for example, not only protects the wearer from the risks associated with ejection but also reduces the force with which he is likely to strike objects within the passenger compartment. It has been observed under controlled laboratory conditions that the restraining action of a lap-type seat belt reduces the force of head blows by as much as one-third (9). If objects and surfaces within the reduced striking range of a seat-belt wearer are designed to absorb energy and to distribute it over a considerable area of the contacting body, a further reduction in injury-producing force is readily obtained. Preliminary studies, utilizing a paired-comparison technique, have indicated that the use of seat belts by nonejected persons is associated with a maximum demonstrable decrease of about 60 percent in risk of all grades of injury (2, 4).

Additional design modifications can be sug-

STRIKER

STRIKER, AND
LATCH ENGAGED

LATCH ASSEMBLY

calculation for the percentage of reduction would have to take into account the sampling bias.

Since the sample was predominantly rural (more than 90 percent of the accidents studied occurred in nonurban areas), the estimated reduction of 25 percent could be directly applied to the 20,528 lives lost annually in rural accidents, a saving of about 5,132 lives each year. However, the full reduction of 25 percent could not be reasonably expected in urban accidents where accident conditions are frequently less severe than on rural roads. It was estimated that perhaps a 10 percent reduction could be presumed, and that about 315 of the 3,150 urban fatalities might be eliminated by prevention of ejection. Thus, a minimum of approximately 5,500 annual fatalities might be avoided in future years if the hazards of ejection were removed.

Discussion

An annual toll of approximately 40,000 deaths and more than 1,000,000 injuries (5, 8)

in motor vehicle accidents is truly epidemic in proportion, and is not likely to be brought under control except by preventive methods affecting a majority of the national population. Obviously, the ideal solution would be the elimination of accidents themselves, but it clearly must be assumed that a certain number of accidents will always take place. Furthermore, large-scale measures to prevent accidents may take years to develop.

If it is admitted that some accidents will always occur despite all efforts, then proper attention to the crash injury problem should include development and provision of controls that will operate to prevent injury when an accident occurs. Controls of this sort may be compared to the use in preventive medicine of serums and vaccines which protect the recipient from the consequences of exposure to infectious diseases.

It is the objective of automotive crash injury investigations to isolate and identify the specific causes of injury observed in injury-producing accidents, and to provide indications of the fire-

Advisory Committee on Radiation

A National Advisory Committee on Radiation was established by the Surgeon General of the Public Health Service February 12, 1958, to advise on programs of the Service in public health aspects of radiation.

Present Service activities in this field include research, epidemiological studies, radiation monitoring of water, air, and milk, and technical assistance to the States on safety measures.

Dr. Russell H. Morgan, professor of radiology, Johns Hopkins University Medical School and radiologist in chief, Johns Hopkins Hospital, who has been serving as special consultant on these matters, is committee chairman. Dr. Donald R. Chadwick of the Office of the Surgeon General is executive secretary.

To-date committee appointments also include: Dr. Arnold O. Beckman, president, Beckman Instruments, Inc., Fullerton, Calif.; Dr. Victor P. Bond, Brookhaven National Laboratory, Upton, N. Y.; Dr. Richard H. Chamberlain, professor of radiology, University of Pennsylvania Hospital, Philadelphia; Dr. James F. Crow, professor of genetics, University of Wisconsin, Madison; and Dr. Herman E. Hilleboe, commissioner of health, New York State, Albany.

Other committee members are: Dr. Hardin B. Jones, Donner Laboratory, University of

California, Berkeley; Dr. Edward B. Lewis, professor of biology, California Institute of Technology, Pasadena; Dr. Berwyn F. Mattison, executive secretary, American Public Health Association, New York City; Lauriston S. Taylor, chief, Atomic Radiation Physics Division, National Bureau of Standards, Washington, D. C.; Dr. George W. Thorn, physician in chief, Peter Bent Brigham Hospital, Boston, Mass.; and Dr. Abel Wolman, professor of sanitary engineering, Johns Hopkins University, Baltimore, Md.

gested, and new developments tested as they become available. At present, data from more than 10,000 automobile accidents are available for use as a control group in evaluating future safety designs.

Although the present report has been concerned with ejection only as it influences the incidence of fatal injuries, the importance of ejection in nonfatal injuries, particularly those that are seriously disfiguring or disabling, should not be overlooked. Unfortunately, data are not available to predict the national reduction in nonfatal injuries that might be expected if ejection should be prevented. However, there is evidence that the percentage of passenger car occupants sustaining serious and critical injuries, whether ejected or not, is roughly the same as the percentage who are fatally injured. Previously published research findings have indicated that the number of fatal injuries sustained by passenger car occupants is similar to the number of serious-to-critical (dangerous) injuries (3). Thus, among those persons injured nonfatally in motor vehicle accidents each year, there might be some 23,670 passenger car occupants whose injuries are in the serious-to-critical range, and whose risk of sustaining injuries of this severity is at least doubled when ejection takes place. (The calculated ratio is 2.5 to 1.) Effective prevention of ejection could scarcely fail to produce a substantial reduction in the annual number of serious-to-critical injuries.

Although it is not a function of the present research in automotive crash injuries to develop the actual devices for control and elimination of the ejection hazard, data and findings suggest the provision of strengthened door locks in currently manufactured cars, automobile seat belts, and some simple and effective device for keeping doors closed on the more than 50 million pre-1956 cars still operating today.

One serious limitation of devices such as the seat belt relates to the educational and psychological difficulties in bringing about their general acceptance and use. Inevitably, a considerable number of automobile users will show more than initial resistance. But it is believed that extensive efforts aimed at encouraging widespread use of seat belts, together with constant modification of automobile components

identified as responsible for injury, will result in a significant reduction of highway casualties.

Application of the means for controlling ejection and its injurious effects is within the realm of immediate possibility. It is hoped that the goal of an annual saving of several thousand lives will provide the needed incentive.

Summary

In a sample of injury-producing accidents analyzed in the Cornell University Medical College study (3,261 passenger cars, each of which contained at least 1 injured person), 13.6 percent of all occupants were completely ejected from an automobile.

Ejected occupants of passenger automobiles had a much higher risk of fatality than those not ejected. This increase was demonstrated to be statistically significant and not due to chance.

The frequency of ejection from doors opened under crash impact conditions varied according to accident severity and seat occupied. Fatality risk was also influenced by these two factors.

Observed and expected fatalities based on a simultaneous consideration of ejection risk, accident severity, and seat occupied demonstrated that prevention of ejection from passenger cars could have reduced fatalities among passenger car occupants in the study by 25 percent.

It is conservatively estimated that about 23,700 of the approximately 40,000 lives lost annually occur among passenger automobile occupants involved in traffic accidents. Of these fatalities, about 20,000 occur in rural areas.

Elimination of ejection in passenger automobile accidents on a nationwide scale could save a conservatively estimated 5,500 lives yearly if the level of annual fatalities persists at about 40,000.

Ejection from automobiles can be prevented by the use of properly designed and installed seat belts, further refinements of the safety door lock which was standard equipment in 1956 and 1957 cars, and auxiliary devices designed to keep doors closed in older cars.

few examples. In the 1950-56 campaign against yaws in Indonesia, more than 23 million persons were examined and $3\frac{1}{4}$ million were treated during the initial surveys, and more than 31 million examined and 1.5 million treated during the re-surveys. In Haiti, until 1950, yaws affected almost a third of the rural population. By December 1954, a total of 2.8 million people had been treated. Observation in the southern region of the country, where the campaign had been initiated, showed that less than 1 percent of the population had contagious yaws.

Similarly with syphilis; in the Ghund Valley (Simla, India) control of this disease was

achieved within a few months. When the entire population of this secluded valley was examined clinically and tested, 65 percent were shown to be positive. Penicillin was administered, and a checkup 5 months later showed that no new clinical cases had occurred.

Good results are being obtained by the use of antibiotics in mass campaigns conducted against trachoma and infectious conjunctivitis, which affect no less than 400 million people throughout the world.

Through the mass BCG vaccination campaigns (about 200 million people have been tested and around 90 million vaccinated) and the application of the new chemotherapeutic

World Health Organization, 1948-1958

At the Eleventh World Health Assembly in May 1958 in Minneapolis, the World Health Organization can look in retrospect at 10 productive years, each increasingly significant to mankind. Through its growing network of activities, whether they are part of the total war against malaria, eradication of yaws, or of environmental efforts less dramatic but equally vital, WHO has left its beneficial mark in the remotest corners of the world. Also high on the list of WHO contributions is an achievement outside the realm of health: the agency has demonstrated a working design for worldwide cooperative action on a common front.

On the occasion of the World Health Organization's tenth anniversary, the following pages are devoted to papers reflecting the agency's dynamic growth and accomplishments. Additional papers will be published following the assembly.

TEN YEARS OF WHO PROGRESS

M. G. CANDAU, M.D., M.P.H., DIRECTOR-GENERAL

• **THE WHOLE CONCEPT** of the World Health Organization and all the principles included in its constitution are based on this simple truth: in our shrunken world, health, like peace and security, is indivisible, and mankind's fight to control and eradicate disease can be won only through the concerted efforts of all of us. Therefore, when WHO was created, arrangements were made for universal membership. Today, with 88 members and associated members, such universality has almost been obtained.

Their cooperative effort has already brought a number of benefits to all. Rapid pooling of information and experience makes it simpler to

contend with diseases such as influenza and poliomyelitis, to meet the threat to mental health that grows from modern conditions of life, to adapt medical education to changing needs, and to study emerging problems such as health hazards of radiation or the mental health aspects of automation.

Countries that are struggling to conquer age-old diseases and to build up modern public health services have benefited further from the practical help given through the World Health Organization. Indeed it is for the successful fight against certain diseases widespread in the tropics and subtropics that the Organization is most widely known. Let me give you a

advanced techniques under conditions as similar as possible to those prevailing in their own countries.

Fellowships provide opportunity for advanced training abroad in varied subjects such as the teaching of preventive medicine, anatomy, and physiology; the organization of public health laboratories; the standardization of biologics; the medical use of radioisotopes; cell metabolism in cancer; food additives; the organization of medical education; thoracic surgery; the control of malaria, tuberculosis, venereal diseases, and congenital heart disease; psychotherapy for juvenile delinquents; psychiatric aspects of asthma; tropical architecture for health institutions; and, of course, post-graduate training in public health, nursing, sanitation, health education of the public, and similar subjects.

A great deal of effort and money has been

devoted to the fellowships program—not only the effort of the countries selecting and proposing candidates and that of WHO planning and administering the individual fellowships, but also, and most important, the effort contributed by countries and institutions of study, without whose goodwill and cooperation the program would not have been possible.

WHO Expert Advisory Panels and Committees

Expert advisory panels were established so that WHO could obtain the technical advice it needed on a particular subject either by correspondence with panel members or by inviting them to expert committee meetings. Tribute should be paid to the farsightedness of those whose idea it was to establish these panels and to those who, as members of them, have individually and collectively provided essential

agents, promising results are being achieved in reducing tuberculosis. As a result of action undertaken by national administrations, often assisted by WHO and other international and bilateral agencies, more than 350 million people can today be considered either freed from or protected against malaria.

Initiated or supported by WHO assistance, these campaigns have been carried out on every continent. One result is that, increasingly, babies are born to live, not to die. Increasingly, people can expect strength to live and capacity to work. In the past 10 years this great new promise has reached out to become reality to ever more millions of our fellow men.

Building Health Services

At the same time, the slower task of building up comprehensive health services is going forward in the member states with support from the Organization so that results achieved against communicable diseases can be consolidated. Most of the coordinating and leadership functions of WHO are directed towards this all-important objective. This fact is reflected in the growing development of inter-country education and training programs for medical and other health personnel and in the fact that today more than 40 percent of our projects in all regions are mainly concerned with education and training. In addition to providing assistance in the establishment or improvement of medical schools, nursing schools, and other training institutions, WHO experts and consultants are reviewing their curriculums and, what is even more important, their effectiveness in relation to local health needs. During the past years, it has been made clear that modern methods of combating disease and promoting health are useful only if their application is satisfactorily adjusted to widely differing stages of social, cultural, educational, and institutional development. Only in this way can the people for whom the measures are designed accept them and put them into practice as an integral part of their own ways of life.

It remains generally true, however, that experience gained in one area can be usefully applied in others. Seminars, conferences, and

study tours arranged on a regional or inter-regional basis, in addition to providing inspiration and stimulus to their participants, are considered to be increasingly useful as vehicles for the exchange of scientific information and experience.

Among the conferences held during the past 10 years to promote medical education was one in New Delhi, where 132 medical education experts gathered to examine the type of training needed to solve India's shortage of medical manpower. A conference held in Chile, and attended by deans and professors from 40 medical schools in South America, discussed the teaching of preventive and social medicine. Israeli medical officers have benefited from the pooled experience of visiting public health workers. Anesthetists from many countries have been and are being trained in special courses in Copenhagen. Physicians have been instructed, also in Copenhagen, in the management of acute bulbar forms of poliomyelitis by the application of Lassen's method. Sanitary engineers have had an opportunity to further their knowledge through seminars organized at Leiden, Milan, and other places. Treponematologists have been given similar opportunities in Stockholm and Bangkok. Malariaologists have received training in Amami, Bukavu, Guatemala City, Lagos, Lisbon, London, Maracay, Mexico City, Rome, and Yaoundé. Many other medical and public health workers have received similar training in a number of countries.

An even more direct form of international training is that afforded by WHO fellowships which enable public health workers to attend, for periods ranging usually from 3 to 12 months and, occasionally, for even longer periods, public health schools or specialized institutions to obtain advanced training or observe new methods and techniques, and bring back to their countries the benefit of their new knowledge. During its first 10 years, WHO awarded 6,396 fellowships. The truly international character of this program is revealed by the fact that during a 1-year period 1,100 fellows were received by 577 institutions in 42 countries. A growing number of fellowships have been devoted to studies within regions, so that fellows can obtain training and become familiar with

WHO Expert Advisory Panels and Committees

Expert advisory panels were established so that WHO could obtain the technical advice it needed on a particular subject either by correspondence with panel members or by inviting them to expert committee meetings. Tribute should be paid to the farsightedness of those whose idea it was to establish these panels and to those who, as members of them, have individually and collectively provided essential

technical advice for the development of the Organization's programs.

The Publications Program

It is important that the new facts obtained by scientists working under the auspices of WHO should find as wide an audience as possible, and the Organization, therefore, has emphasized its publications program. Besides the Technical Report Series (in which the reports of the expert committees appear), the program includes the *Bulletin*, which is a scientific periodical; the *Chronicle*, which contains a monthly account of work carried out under the auspices of WHO in various parts of the world; the *International Digest of Health Legislation*, which contains health legislation texts in full or in summary form; the *Epidemiological and Vital Statistics Report*, and the *Annual Epidemiological and Vital Statistics*, which contain mortality and morbidity statistics from

many countries. There are also the individual books such as monographs on maternal and mental health, plague, influenza, poliomyelitis, biology of treponematosiis, meat hygiene and toxic hazards of certain pesticides to mention to list only a few. These publications contain not only results of work undertaken under WHO auspices but also material from outside contributors concerning facts and studies which may be usefully disseminated to public health workers in all countries.

The publications program forms part of WHO's worldwide services from which even the most advanced countries can benefit. These services comprise the recommendation of international standards for biological substances; establishment of specifications and the selection of nonproprietary names for the more important pharmaceutical preparations coming on the market; and control of air, land, and sea traffic from the point of view of health. The collection and study of comparable health statistics from as many countries as possible and technical advice concerning addiction-producing drugs and their control are also WHO services.

International Standardization

The publication of the first volume of the *Pharmacopoea Internationalis* and the adoption of the International Sanitary Regulations—both historic events occurred during 1951—are examples of the benefits which can derive from an international health organization, and which scarcely could have been achieved without it.

Approving the publication of the International Pharmacopoeia in May 1950, the Third World Health Assembly recommended "the eventual inclusion of its provisions in the national pharmacopoeias after the adoption of the said provisions by the authorities responsible for the pharmacopoeias." It is thus recognized that the International Pharmacopoeia (of which the second volume was published in 1955) constitutes only a recommendation: its specifications are not intended to be legal in any country but are intended mainly to serve for reference purposes when national specifications are established.

The specifications for pharmaceutical prep-

arations published in the International Pharmacopoeia are all the more useful these days when international travel is on the increase, when one new medical advance follows another in rapid succession, and when countries want to take the maximum advantage of the therapeutic progress in other countries.

The biological standards for which WHO is responsible already cover scores of substances, and new ones come continually under review by the Expert Committee on Biological Standardization and by the research institutes charged with making assays.

The Organization has a special duty to discourage unnecessary use of drugs which are likely to produce addiction. It is the authority which advises whether a new substance is addiction producing or not, and its advice is given legal force by nations that are parties to the international conventions as set up by the League of Nations and the United Nations.

WHO can, and does, issue warnings about substances liable to lead to harmful habits and recommends that appropriate safeguards be applied until it can be finally established to what extent they are dangerous to public health. For example, the Organization's continual watch on the abuse of the barbiturates, amphetamines and, more recently, the so-called tranquilizers resulted in relevant resolutions of the United Nations Commission on Narcotic Drugs.

New Sanitary Regulations

The new International Sanitary Regulations drawn up by WHO represent the first overall agreement between the countries on effective and uniform means of preventing the spread of disease across frontiers. They have reduced a confused and conflicting mass of cumbersome conventions to a single, international, legal in-

technical advice for the development of the Organization's programs.

arations published in the International Pharmacopoeia are all the more useful these days when international travel is on the increase, when one new medical advance follows another in rapid succession, and when countries want to take the maximum advantage of the therapeutic progress in other countries.

The biological standards for which WHO is responsible already cover scores of substances, and new ones come continually under review by the Expert Committee on Biological Standardization and by the research institutes charged with making assays.

The Organization has a special duty to discourage unnecessary use of drugs which are likely to produce addiction. It is the authority which advises whether a new substance is addiction producing or not, and its advice is given legal force by nations that are parties to the international conventions as set up by the League of Nations and the United Nations.

WHO can, and does, issue warnings about substances liable to lead to harmful habits and recommends that appropriate safeguards be applied until it can be finally established to what extent they are dangerous to public health. For example, the Organization's continual watch on the abuse of the barbiturates, amphetamines and, more recently, the so-called tranquilizers resulted in relevant resolutions of the United Nations Commission on Narcotic Drugs.

New Sanitary Regulations

The new International Sanitary Regulations drawn up by WHO represent the first overall agreement between the countries on effective and uniform means of preventing the spread of disease across frontiers. They have reduced a confused and conflicting mass of cumbersome conventions to a single, international, legal in-

strument applied to trade and travelers. They have tested a flexible technique of acceptance of international regulations through adoption by the World Health Assembly, as a replacement for the old, slow negotiation of many separate treaties. They have achieved some measure of harmony with modern epidemiological and public health practice. And they have contributed to the abandonment of a number of questionable technical and administrative requirements.

The epidemiological intelligence service is another example of what can be achieved through international cooperation. Governments communicate regularly to WHO information concerning cases of and deaths from quarantinable diseases. This is re-transmitted by a worldwide network of radio stations at WHO's disposal. In addition to radio messages, a printed bulletin, the *Weekly Epidemiological Record*, is sent to more than a thousand quarantine and health officers in various parts of the world. More complete notifications of particular interest to certain areas are also distributed weekly in printed or mimeographed form from Singapore, Alexandria, and Washington. This system enables maritime and airport officers anywhere to institute the necessary measures of protection, without interfering unduly with international traffic.

Concerted Effort Against Disease

With present technical developments, the control of diseases has gained new impact. One may take as an example recent developments in malaria control.

Although 230 million people have been freed from or protected against malaria, further efforts to bring safety to the more than 370 million people still exposed must reckon with the fact that certain anopheline mosquitoes have become resistant to residual insecticides. The alarming growth of this problem may be illustrated by the steady increase of resistant species of public health importance from 2 in 1946 to 38 in 1956. The problem is increasing in complexity and magnitude more rapidly than progress is being made, and not a single practical solution has been forthcoming except switching from one insecticide to another.

The WHO Technical Conference on Insect Resistance, which met in Geneva during the summer of 1957 to consider an international collaborative program of research, agreed that such a program is not only urgently needed but is essential for practical solutions in the foreseeable future of the many resistance problems.

An important fact in this context is the dynamic nature of the resistance problem as opposed to the more static nature of many of the scientific and technical problems facing the world today. The problem of the common cold, for example, may not be solved within the next decade; the problem itself is unlikely, however, to become more serious on that account. The resistance problem, on the other hand, intensifies day by day, and, as a consequence, it would be irresponsible to dismiss the real possibility of a significant increase in the incidence of vectorborne diseases of man.

Since the historic resolution on malaria eradication of the Eighth World Health Assembly (1955), more and more countries have accepted the objective of eradication as the goal of their antimalaria activities and, by the end of 1957, 76 countries and territories were either implementing or planning a program of malaria eradication. Their aggregate population represents 73 percent of the total population of all countries and territories where malaria is, or has recently been, present. There is no alternative to this course since the eradication of malaria from a single country can only be partially successful unless the same result is achieved by its neighbors and the danger of reinfestation thus eliminated.

What is true of malaria is equally true of other diseases, and there are signs that a concerted international attack on tuberculosis, leprosy, poliomyelitis, influenza, rabies, and many other diseases may turn out to be not only the most efficient, but ultimately also the most economical approach to the control of these diseases.

WHO as a Coordinator

Among examples of international coordination benefiting all countries are the International Treponematoses Laboratory Center, a

Teams working in the WHO campaign for the eradication of yaws have examined, up to 1957, more than 60 million people in tropical regions and treated some 15 million. Typical is this Nigerian child, who, 10 days after receiving an injection of penicillin, is almost completely rid of sores.

established with WHO assistance at the Johns Hopkins University in Baltimore, Md., and the WHO Serological Reference Laboratories in Copenhagen, Denmark, and Chamblee, Ga. These laboratories are currently collaborating with many national laboratories on a number of thorny problems with WHO as coordinator. Worthwhile results have been obtained in connection with the new treponemal agglutination test, the immunological relation between the various treponematoses, penicillin sensitivity of treponemal strains received from various WHO field projects; the production and standardization of cardiolipin antigens, establishment of

standard test serums, the evaluation of antigens for the serodiagnosis of syphilis, and many other subjects of research. An internationally assisted project against endemic syphilis in Bosnia has yielded new and valuable epidemiological knowledge.

The International Salmonella and Escherichia Center in Copenhagen receives cultures for identification from all parts of the world and distributes cultures and diagnostic serums to national laboratories. The worldwide network of WHO Influenza Centers regularly examine strains of influenza virus from all countries and communicate valuable information on the types

of strains which have to be used at particular times and in particular places in the national production of vaccine.

The influenza epidemic in 1957 subjected this network to its most serious test since its inception in 1947. However, it successfully performed the functions for which it was designed with the result that further development seems justified. In just less than 3 weeks after WHO received the first news that a significant epidemic was occurring, the Organization was able to inform health authorities and vaccine-producing laboratories that the responsible virus was unrelated to all previously isolated strains and that existing vaccines were unlikely to give protection. The warning was given in time for several countries to prepare their health services to face the impending epidemic and, in some countries, significant quantities of vaccine were produced in time for use before the epidemic struck.

Because of the uncertain status of domestic animals in the epidemiology of human influenza, steps were taken early in last year's epidemic to have serum specimens collected from swine and horses in 25 countries before and after the human epidemic struck. These specimens are being examined at the WHO Influenza Centers and it is hoped that valuable information will be gained concerning the epidemiology of human influenza.

New Public Health Activities

The example of influenza shows that, even in regard to what we may call the old, traditional disease problems, it is the duty of WHO to keep pace with current scientific developments and progressively to modify its approach to specific disease problems in the light of both new discoveries and the changes which may occur in epidemiological conditions. In our struggle to achieve worldwide health and prosperity, there is no room for complacency. We must be constantly alert and ready to attack any new problem which arises.

Increasingly in the years to come emphasis will be laid on the importance of certain new health activities in which the Organization is being called upon to collaborate with govern-

ments, such as chronic diseases, occupational health, mental health, food and drug services, and the health aspects of nuclear energy. In discharging its responsibilities with regard to the health aspects of atomic energy the Organization greatly benefits from methods and techniques already evolved in other fields for the training of personnel, the dissemination of scientific information, and the stimulation and coordination of research. This experience has been carefully applied to the two main types of activity WHO is required to carry out in developing a program on health in relation to atomic energy: The first relates to the use of radioisotopes in medicine and public health; the second aims at the protection of populations against the risks of radiation. From the directives of the World Health Assembly it is clear that WHO is concerned only with the health aspects of the peaceful use of atomic energy.

Training, especially of personnel from countries new to atomic energy, is considered as one of the most important functions of WHO in this field. An initial step was taken in 1955 when the first international training course ever held on radiation protection in relation to atomic energy was organized by WHO. This was held in Stockholm with the cooperation of the Swedish Government and the United States Atomic Energy Commission, and in 1957 a similar course was given at Mol in Belgium, with the cooperation of the Belgian Government as well as with the USAEC. Both courses were attended by physicists and physicians specializing in radiation work from a number of European countries, while in the case of the Mol course representatives of some Eastern Mediterranean countries also took part. WHO has also arranged rather shorter courses for public health administrators at Saclay, France, and Harwell, England.

Activities last year included two expert committees convened for the general purpose of providing more detailed recommendations on the type of training which doctors and other health workers would require in a world in which the peaceful use of atomic energy and radiation in general is likely to take a progressively more important place. One of these

committees dealt with the introduction of radiation medicine into the undergraduate curriculum, the other with the subject of postgraduate training in the public health aspects of atomic energy.

Training of medical men in the use of radioisotopes in countries new to this application of science is a subject where WHO's system of international fellowships is particularly useful, both to introduce a fellow to the requisite techniques and to give him clinical experience. Long-term individual fellowships are also most useful in training medical men or scientists in radiobiology.

The interest of the World Health Organization in radiation and human genetics was shown by the convening in 1956 of a study group on the effect of radiation on human heredity, and the report of this group has been recently published. The genetic effect of radiation is of course one of the factors to be considered in the disposal of radioactive waste or in the possible effects on populations of the widespread

use of medical irradiation, and is therefore of direct concern to public health administrators.

The Future

During the first 10 years, the World Health Organization has fulfilled international tasks taken over from its predecessors; but it has also undertaken a program towards a healthier world beyond anything previously attempted. Together with other international agencies, WHO has helped reduce the gap that separates the people of the well-to-do countries from their less fortunate brethren. It has carried on and enriched the tradition of the universality and humanitarianism of medical science, and its modest achievements have at least shown some of the possibilities opening up for good and effective international health cooperation.

We realize, however, that much more is urgently needed before the whole world may enjoy the degree of health protection that is available to an increasing yet still far too small segment of mankind.

Manila Meeting on Social, Preventive Medicine Teaching

Deans of medical schools and professors of social and preventive medicine in Western Pacific countries met at the University of Manila during 2 weeks of October 1957 to discuss the teaching of social and preventive medicine to undergraduate students. Represented in the study group, which was sponsored by the World Health Organization, were Australia, Cambodia, China (Taiwan), Fiji, Hong Kong, Japan, New Zealand, Singapore, the Philippines, and Vietnam.

As stated by the group, social and preventive medicine courses should make students aware of social needs in medical services and of the role of social organization in the genesis, course, distribution, prevention, and treatment of disease.

Several recommendations emanated from the

conference: the teaching of social and preventive medicine, which must vary according to the country's needs, should have a practical approach. Courses should extend throughout the medical curriculum and retain some traditional public health material. In research, applied and fundamental studies should be balanced.

Advantage should be taken of opportunities to teach through local health centers, teaching hospitals, and other community resources.

The medical school should teach comprehensive health care by using existing services of the government or other agencies, and under some circumstances, by using their own health clinics.

A full report will be issued by the study group.

CHILD HEALTH

JESSIE M. BIERMAN, M.D.

MARTHA M. ELIOT, M.D.

FROM THE TIME that the Technical Preparatory Committee established by the United Nations met in Paris in March 1946 to prepare a draft constitution for the World Health Organization, it was a foregone conclusion that one of the major purposes of the World Health Organization would be to promote the development of maternal and child health programs, with national agencies and with other international organizations cooperating to this

Dr. Bierman, who served as chief of the Maternal and Child Health Section of the World Health Organization in Geneva during 1956-57, is professor of maternal and child health, University of California School of Public Health. Dr. Eliot heads the maternal and child health department of the Harvard School of Public Health. She has served as assistant director-general of the World Health Organization and as chairman of its Expert Committee on Maternal and Child Health.

end. Two clauses in the proposals of that committee made this quite clear.

In the preamble, after defining health and setting forth a series of declarations with respect to the rights of individuals to health, the responsibilities of States and related truths, the preparatory committee proposed inclusion of the statement, "Healthy development of the child toward world citizenship is of paramount importance." This proposal both in the committee and on the floor was submitted as part of the draft constitution to the International Health Conference, held in New York in June and July 1946.

During the discussions at this conference this proposal became the subject of active debate in committee and in plenary sessions. As a result the words which were obviously subject to disagreement—"toward world citizenship"—were dropped, and, instead, a new phrase was substituted to express the primary intent of the original language, namely, that all children must develop the ability to live harmoniously with their neighbors and with all peoples throughout the world. Because of the importance of this concept to all the world today, it is desirable to state here the language as it was finally adopted by the International Health Conference and made a permanent part of the constitution of the World Health Organization. The sixth clause of the preamble says: "Healthy development of the child is of basic importance; the ability to live harmoniously in a changing total environment is essential to such development." Fortunately, also, since preambles are sometimes thought of as aspirations only, the framers of the constitution included in the list of functions of the Organization the same concept in words calling for action. Here the words are: "To promote maternal and child health and welfare and to foster the ability to live harmoniously in a changing total environment."

It should be remembered that this constitution was adopted in July 1946, only a few months after the first atomic bomb had been dropped on Hiroshima. In presenting arguments for the adoption of this reworded clause for the preamble, Dr. Brock Chisholm, the delegate from Canada, pointed out the complete change in the situation in the previous 2 years.

Dr. Chisholm went on to say: "The environment of every person in the world now is the whole world; and it is essential to the health of every individual that he develop beyond the capacity to live with his own kind of people in his own little environment and be able to live with all kinds of people all over the world."

He continued: "This is not a social or an educational concept. It is a health concept, because no person who is incapable of doing this will in the future be able to live at peace with himself—because over the radio, through newspapers, by movies, he is brought into immediate contact with everything that goes on all over the world, and he must be able to live in harmony with these things in order that he may not suffer the results of frustration of his own gregarious instinct. . . . It has been necessary for every organism to be able to change and adjust to a changing environment throughout all time. If man proves unable to make this adjustment, he will follow the dinosaur into oblivion and will become completely obsolete."

When he supported Dr. Chisholm's proposed new wording, as indeed many delegates did, Dr. Frank Boudreau, speaking for the United States, expressed the hope "that the World Health Organization would undertake as soon as possible a program of work designed to achieve its objective."

It was with this as a frame of reference, then, that the work of WHO in the field of maternal and child health got started. The first steps were taken by the Interim Commission, which had been established to act until enough countries ratified the new constitution to bring the World Health Organization itself into existence. The first proposals were to pick up the type of activity that had been carried out by the Health Organization of the League of Nations, namely, studies of infant mortality.

However, by January 1948, before these studies could be begun, more comprehensive proposals for a new maternal and child health program to be undertaken by the World Health Organization were already under consideration at the fifth session of the Interim Commission in anticipation of the First World Health Assembly which was expected to be held the following June. Substantial interest had been growing among members of the commission in

CHILD HEALTH

JESSIE M. BIERMAN, M.D.

MARTHA M. ELIOT, M.D.

FROM THE TIME that the Technical Preparatory Committee established by the United Nations met in Paris in March 1946 to prepare a draft constitution for the World Health Organization, it was a foregone conclusion that one of the major purposes of the World Health Organization would be to promote the development of maternal and child health programs, with national agencies and with other international organizations cooperating to this

Dr. Bierman, who served as chief of the Maternal and Child Health Section of the World Health Organization in Geneva during 1956-57, is professor of maternal and child health, University of California School of Public Health. Dr. Eliot heads the maternal and child health department of the Harvard School of Public Health. She has served as assistant director-general of the World Health Organization and as chairman of its Expert Committee on Maternal and Child Health.

A Turkish mother soon to have her ninth child is shown here receiving prenatal care for the first time. Set up with the help of WHO and UNICEF, the mother and child center in Ankara is now carried on by the national staff.

In July 1948 the First World Health Assembly, recognizing that certain difficulties in the relationships between the two organizations had arisen and might continue unless a framework for appropriate and continuous cooperative action were set up, recommended the establishment of a Joint Committee on Health Policy to be composed of members of the executive boards of the two organizations. Later in the same month these executive boards, meeting simultaneously in Geneva, Switzerland, adopted essentially similar resolutions creating the Joint Committee on Health Policy of the two organizations.

In brief, the functions of this committee are to approve all health programs through which

UNICEF proposes to meet the requests of countries for assistance and to review these programs from time to time with a view to their evaluation. The committee also assures that the organizations are continuing to work cooperatively to the end that children the world over will receive the best health care possible under the circumstances in the country seeking help. The health programs that have been approved for joint projects fall into three groups: (a) mass health campaigns, such as those for control or eradication of malaria, tuberculosis, yaws and other treponematoses, trachoma, and leprosy; (b) maternal and child health (or welfare) programs, including establishing, equipping, and providing supplies for

a program of maternal and child health that would be more in keeping with the intent of the constitution and that would lay the ground for cooperation with many countries.

By January 1948, it had also become clear that the World Health Organization would have an increasing responsibility to provide the professional and technical help required by United Nations International Children's Emergency Fund in connection with its programs in the child health field. A comprehensive plan for the development of a maternal and child health program (1) over the next few years was therefore laid before the Interim Commission. Its warm reception resulted in maternal and child health being placed in the priority list of recommendations for program action second only to malaria, which was well known to be the world's greatest killer. In the introduction to its proposal, the Interim Commission said:

"An international programme for maternal and child health is recommended in view of the high incidence of preventable deaths among infants and mothers in large areas of the world; the effectiveness of available techniques in reducing mortality and improving the health of infants and mothers; the immediate and continuing need, for the protection of coming generations, of scientific guidance in the utilization of available foodstuffs; the high incidence of communicable and other preventable diseases among children; the widespread mental and emotional maladjustment and insecurity among children and youth; the insufficient understanding and knowledge among parents and others of the causes of ill-health and abnormal behavior of children; and the effects of economic and social changes on the physical, mental and emotional development of children."

The objectives of the proposed program were:

"To assist governments in developing services and facilities that will assure adequate maternity care, the best possible chance of survival to infants, and to all children normal physical growth and development, mental and emotional health, and freedom from preventable diseases; to pool knowledge, acquire new facts, develop standards of care, and distribute information in respect of all relevant matters; and

to cooperate with other agencies on joint undertakings which apply knowledge and techniques in the fields of social and biological sciences and of education to problems of maternity and childhood."

The commission recommended the establishment of a section on maternal and child health as a part of the WHO Secretariat, the establishment of an expert advisory committee on maternal and child health, and the employment of individual experts and teams on a temporary basis as required.

The First World Health Assembly, when adopting in July 1948 its program for the first year's work, included maternal and child health among the four top priority programs, and instructed its executive board to take the steps necessary to implement the commission's recommendations. The story of the work for children done by this and other sections of WHO is described later.

Reference must be made here, however, to the establishment of UNICEF and to the effective collaboration that gradually developed between the Fund and WHO, particularly with the Maternal and Child Health Section. Fortunately for the world's children the General Assembly of the United Nations decided in December 1946 to create a fund to which governments and people would contribute voluntarily for assisting children in war-devastated countries with food, clothing, and medical supplies, for training personnel, and for child health purposes generally. That this new organization must necessarily collaborate with WHO and other appropriate specialized agencies of the United Nations was foreseen by the General Assembly.

The resolution under which UNICEF was established provided that the Fund should be primarily responsible for making available equipment and supplies and for assisting with training, but that it should look to the specialized agencies, especially to WHO, for the technical help and assistance required by countries seeking assistance for the development of their child health and welfare programs. It became necessary very early for these organizations to develop methods of cooperation that would assure satisfactory relations with governments and with each other.

more developed countries a hundred or more years ago. The principal child health problems are the result of undernutrition and malnutrition combined with an endless procession of infectious and parasitic diseases. Underlying these are poverty and ignorance and a generally unsanitary environment.

MCH Assistance Matches Development

There has been no uniform plan of MCH assistance. In countries with minimal educational and health facilities, few professional health workers, and high prevalence of endemic and communicable diseases, the mass disease control campaigns have had high priority in the beginning. The first MCH assistance has often centered about improvement of any existing, voluntary services. This is followed by the establishment of training facilities for auxiliary MCH workers; simple measures for improving the services of traditional birth attendants, or untrained midwives; and extension of preventive services, especially in maternity care, to new areas as personnel are trained. Fellowships for study abroad have provided a nucleus of professionally qualified doctors, nurses, and midwives. Then, as rapidly as possible, training schools for professional nurses and midwives are established.

A later phase of assistance is the planning and establishment of a permanent health organization to consolidate the gains made in the mass campaigns and to provide a framework for the extension of preventive and curative services and health education. It is in this stage that maternal and child health has made a great contribution to general public health, for it is commonly the first of the permanent preventive health services and forms a nucleus around which general community health programs can be built. In the region of the Americas, emphasis has been on strengthening MCH services as a component part of general health projects.

In the majority of assisted countries at present, basic minimal services are being extended to rural populations as rapidly as possible, and at the same time professional training is being stepped up so as to provide more adequate numbers of professional personnel for super-

vision of the ever-increasing numbers of local centers and for leadership within the countries.

A small group of the assisted countries, such as Austria, Italy, and Spain, have achieved virtually full coverage of the population by basic health services including maternal and child health. Their infant and maternal mortality rates are relatively low. In these, the requests for assistance are in connection with the development of services for prematurely born infants, the rehabilitation of physically handicapped children, the prevention of childhood accidents, and in the promotion of mental health. The assistance has been in the form of travel fellowships, seminars and inservice training courses, short-term services of experts, and the provision of equipment necessary for establishing programs in these special fields.

Between 1947 and 1956, some 600 WHO fellowships were awarded for study abroad of various aspects of maternal and child health. The majority have been awarded to physicians, but nurses, midwives, and a few other categories have been included. The fellows came from 44 countries and territories and studied in 27 different countries.

International personnel have been assigned to 34 countries to assist the governments in establishing or improving their own training institutions for nurses or midwives. And medical schools in 10 countries have had help in establishing or upgrading departments of pediatrics. Assistance in pediatric education can be expected to increase as the UNICEF Executive Board has recently approved the extension of its assistance to medical schools for the training of physicians in pediatrics and preventive medicine. The first of these joint WHO and UNICEF projects is the one at the University of Madras, India. The pediatric department is envisaged as a focal point for the teaching of pediatrics to nurses and midwives as well as physicians, for continuation education for MCH field personnel, for graduate training of pediatrics instructors and for research on the important child health problems of the country.

Assistance has also been given to the All India Institute of Hygiene and Public Health in Calcutta where an MCH unit has been es-

maternal and child health centers, training personnel for this type of work, and providing personnel for demonstrations of newer methods of health work with mothers and children; and (c) certain of the food conservation programs, which are carried out largely in collaboration with the Food and Agriculture Organization of the United Nations.

In the past 10 years of their collaboration, these two great international organizations have assisted in the development of many different types of programs that affect the health and well-being of millions of children and mothers in many parts of the world.

Broad Scope of MCH Programs

The mass campaigns against the major communicable diseases and programs to improve the sanitation of the environment are of basic importance to the health of children. But much more is required than the stilling of epidemics. To achieve the stated objectives, it is necessary to reach and to serve the individual child and his family on a continuing basis. This requires some kind of permanent organization in the field and large numbers of trained personnel. At best, this is a painstaking and costly process and it takes time, not only to train personnel but to build services and to gain acceptance and cooperation of the people served. To be most effective MCH services need to be an integral part of general health and medical services of the community, and in many areas of the world such services are in the very early steps of development or are still nonexistent.

During the earlier years, many maternal and child health centers were established on too specialized a basis in advance of general public health development. But there is now increasing recognition that in the developing countries, maternal and child health should not be considered so much a specialty as a medium through which general health measures can reach two large groups in the population having certain special needs in addition to those shared by all. Children under 15 years of age and women of childbearing age constitute between 60 and 65 percent of the population in most of the assisted countries. Because of the prevalence of endemic diseases and malnutri-

tion, purely preventive services focused primarily on the reproductive and growth processes are neither possible nor desirable. But the thousands of MCH centers which have been established as a result of WHO and UNICEF assistance offer unequalled opportunities to combine preventive and simple curative services with health education and provide focal points for activities in home sanitation, nutrition, and communicable disease control for families.

The amount of funds and the size of the staff in the WHO Secretariat entrusted with this gigantic responsibility have been very small. Positions have been provided for two MCH physicians at headquarters and in the vast region of Southeast Asia and one in each of the remaining five regions. In 1956 approximately 11 percent of WHO and UN technical assistance funds expended in the assisted countries were specifically earmarked for maternal and child health (2). Maternal and child health, nursing, including midwifery, and nutrition services combined account for roughly one-fourth of the funds expended in the assisted countries, or about \$1.6 million. During this same year, UNICEF assistance to the building of permanent services in the MCH field amounted to \$3.4 million, or about 18 percent of the program allocations (3).

As previously noted, most of the assistance in maternal and child health is of a joint nature with WHO responsible for providing professional staff and technical guidance and fellowships for professional training and UNICEF the necessary equipment, supplies, transport, and training stipends for local auxiliary personnel. In terms of funds then, the assistance from the two agencies has amounted to less than \$5 million a year, but it must be borne in mind that the assisted countries have expended far more than this as their share of the cooperative effort.

What follows is an account of some of the contributions which WHO and UNICEF have been able to make in assisting governments of some 50 countries in the development of health services for mothers and children. In these countries live above one-half of the children of the world. The vast majority of them live in areas where the infant and childhood mortality rates are at levels which prevailed in the

In the fight against infant mortality, WHO-trained public health nurses score their first victories when they establish confidence and cooperation. Here, such a public health nurse visits a family living in Chorrera, Panama.

gated to it by member governments and the United Nations. These include coordinating and regulatory functions; collection and distribution of information; pooling of health knowledge, skills, and resources of member countries; and conducting investigations. For want of better terms, these are often referred to as central technical and advisory services. Many of the services rendered by the various headquarters sections make important contributions to maternal and child health. Among them are the statistical services, studies and surveys of nutritional problems and of specific diseases affecting children, mental health, and health education.

Among the chief functions of the MCH Section are the servicing of the expert panel and expert committees in maternal and child health,

the convening of study groups, the conduct of surveys and studies, the development of long-range plans for the MCH program of the organization, and cooperating with other United Nations agencies and with nongovernmental organizations concerned with international programs for children.

There are at present 42 experts from 20 countries on the MCH panel. They include leading authorities in such special fields as prematurity, nutrition, mental and school health, rehabilitation, pediatric and obstetric education, and MCH administration. Other expert panels, such as those in nutrition, mental health, and nursing, also deal with problems of concern to MCH. Through the panel system, the organization has at its command a great wealth of knowledge and skills which it is able to call

tablished to provide graduate training in MCH for physicians and nurses, with emphasis on the child health aspects. The institute is now training students from a number of countries in Asia. Continued progress will demand more opportunities of this kind for MCH physicians to receive training in general public health and the administrative aspects of MCH as well as in obstetrics and pediatrics.

Service and training functions are combined in the MCH demonstration and training projects, 40 of which have been established in 29 countries. In these, WHO has provided a team consisting of an MCH medical officer and usually one or more public health nurses and midwives. The team works with personnel provided by the government. They establish an MCH unit to demonstrate services appropriate for the area and to provide training for auxiliary MCH workers and orientation and refresher courses for professional personnel.

In many of the countries the great majority of deliveries are attended by untrained traditional birth attendants. Training programs have been established in several countries with WHO-UNICEF assistance to bring about a much needed improvement in the practice of these attendants, the program in the Philippines being to date the most extensive and successful. More than half of the estimated 6,000 attendants have had some training.

An essential feature of all of these training plans is that government counterparts work closely with the international personnel and carry on after the withdrawal of the latter which takes place after 2 to 4 years. The physicians, nurses, and midwives who have been assigned by WHO to these training projects have come from all parts of the world. An MCH team working in India may have a physician from Mexico, a nurse from New Zealand, and a midwife from Sweden. While in the early years, the personnel were recruited principally from the United Kingdom, northern Europe, and North America, many other countries are now able to provide personnel with the requisite training and experience to serve in these posts, adding substantially to the international character of the programs.

There can be no question but that international aid has given a tremendous stimulus to

the training of health workers—1,500 nurses and more than 2,000 midwives in a year's time in India; 650 midwives in Korea; 69 health visitors in Syria; the first class of 11 community midwives graduated in Libya; and 10,000 rural auxiliary nurse midwives in Turkey by 1970. A large number of new training schools and field training units have been established. The enrollments for both professional and auxiliary workers have greatly risen, and refresher courses and inservice training programs are increasing. Educational standards for the professions have been raised. The status of nursing as a career for women has improved. And as a result of the increased numbers of professional and auxiliary health workers, it has been possible to establish thousands of new centers in areas where MCH services have never before been available.

Growth of National MCH Units

A central purpose of all WHO assistance is the strengthening of national health administrations. An evidence of progress in this respect, as well as increasing recognition of the importance of maternal and child health, is the creation of MCH units in national health administrations. Twenty-eight of the 53 governments which have had maternal and child health assistance from WHO have established such units or have plans to do so shortly. Twelve of these have been established within the past 5 years.

The functions of the units vary widely, as do the number and qualifications of the personnel. In many instances, the staff consists of only one medical officer, who serves as adviser to the national administration and has certain limited administrative functions. In several Asian and Latin American countries the staff is larger and is able to assume responsibilities for program development and to provide technical supervision of MCH activities.

There are a few countries now in which well-qualified public health workers are not being fully utilized because the governments have been unable to establish the positions for which the personnel were trained.

In addition to direct assistance to governments, WHO has other responsibilities dele-

practices; the influence of long-established traditional child-rearing practices on mental health; and the effects on mental health of the profound changes in every aspect of life which are resulting from rapid technical development.

As international activities increase, the need for coordination of efforts grows. This has been particularly true for the several United Nations agencies, most of which serve children in some way. Excellent cooperative relationships have developed among agencies working on common projects as exemplified by the WHO-UNICEF partnership in MCH assistance programs, WHO-UNICEF-FAO collaboration in nutrition projects, and the WHO-UNESCO study of teacher education in health.

Several nongovernmental international agencies interested in MCH are affiliated with WHO, an arrangement which facilitates cooperative relationships and endeavors. The joint sponsorship of the survey of pediatric education with the International Pediatric Association and the close relationship with the International Union for Child Welfare are examples. In time, it is likely that these coordination functions will become increasingly important.

Never before have opportunities been afforded health workers from most of the countries of the world to meet together, to talk over common problems, to share experiences, to learn from one another, and to arrive at agreements on common goals. In the course of a year there are innumerable opportunities for such interchange offered under WHO auspices—from the World Health Assembly itself and the associated technical discussions involving persons from all member countries, to small seminars and inservice training sessions for local health workers within the countries.

A better understanding of the nature of the health needs of mothers and children and of methods for dealing with problems give administrators courage to deal with the many obstacles in the way. Leaders in MCH benefit from opportunities to keep up to date and to grow in confidence and in professional competence. And for staff workers, confronted every day with sick, malnourished mothers and children, with inadequate funds and staff, and often with little community appreciation or un-

derstanding of their work, the opportunity to meet occasionally with confreres with similar interests and problems provides much needed encouragement and refreshment. It may well be that the widespread opportunities being afforded for the exchange of ideas will, in the long run, prove to be a greater force in the solution of the world's health problems than advice from experts and supplies and equipment.

It appears justifiable to conclude that substantial contributions to child health have been made during the first 10 years of the existence of WHO and UNICEF. While in most of the assisted countries, only a bare beginning has been made toward reaching the objectives set forth by the Interim Commission, it is, nevertheless, a sound beginning. In order that children can learn to "live harmoniously" in their environment, it is necessary first that they live. It is understandable then, that the major effort in a large part of the world has been directed to this end and to laying the groundwork upon which—as time and resources permit—can be built those services which will promote the health of children in the broadest sense.

on at all times for advice and assistance in the determination of policy and on specific matters.

From time to time expert committees of panel members and less formal study groups are convened to study and make recommendations on specific topics. This process of synthesizing existing knowledge on leading problems and making the results widely available through technical reports is a contribution of great importance. A list of subjects most directly bearing on MCH will serve to indicate the broad scope of the problems which have been considered to date (the numbers represent the WHO Technical Report Series designation): maternity care (51), midwifery training (93), prematurity (27), immunization (6, 61), nutrition (44, 72, 97), mental health (70, 75), physically handicapped (58), epilepsy (130), school health (30), MCH administration (115), childhood accidents (118), and pediatric education (119). Many other reports, particularly those dealing with specific diseases affecting children, have also made important contributions to child health.

Several monographs in the MCH field have reported on studies carried out, in various parts of the world, on behalf of WHO (4-8).

In addition to the influence of the published reports, the bringing together of experts and research workers from various parts of the world has had a great influence in focusing attention on unsolved problems, in stimulating research, and in advancing knowledge more rapidly than has heretofore been possible. A good example is the rapidity with which knowledge has accumulated concerning protein malnutrition in children since 1949. Through a combination of WHO-FAO Joint Expert Committee meetings, field surveys, and the bringing together of research workers from all parts of the world under the auspices of the Josiah Macy, Jr., Foundation, protein malnutrition has come to be recognized within a very few years as one of the most widespread public health problems in the world.

WHO has sponsored two surveys of pediatric education, one in Latin America and the other in the countries of western Europe. The latter was carried out under the auspices of the International Pediatric Association. The convening of a study group on pediatric education in

1956 followed the completion of the surveys. These efforts are part of long-range plans to bring about improvements in pediatric education.

Two reviews of WHO-UNICEF assistance in maternal and child health have been carried out by the staff. The last one was presented to the Joint WHO-UNICEF Committee on Health Policy in 1957 (5). The committee has requested that reviews of certain aspects of the assistance program be presented every other year, thus establishing a pattern of continuing evaluation. If properly supported and well conducted, these evaluation studies will have great influence in guiding the two agencies and the assisted governments as well. This is but one evidence of the growing recognition on the part of both WHO and UNICEF of the need for evaluation of the programs which have grown so rapidly in the past few years.

Long-range plans have been developed for studying a number of MCH problems of worldwide significance. Included are the diarrheal diseases which account for the largest number of deaths of infants and young children in most of the developing countries. The epidemiological, clinical, and bacteriological aspects will be studied with a view to defining more clearly the environmental and host factors which must be considered for practical control in the assisted countries. In the region of the Americas, technical discussions and country seminars on diarrheal diseases have been held and field studies are under way to determine the feasibility of teaching auxiliary field workers techniques of combating dehydration, the immediate cause of death in infant diarrheal infections.

Other studies under way are concerned with a reevaluation of present criteria for prematurity, practical approaches to school health in developing countries, methods for strengthening nutrition services in MCH programs, and methods for improving the preparation of midwives for services to children.

The incomparable opportunities for research in the international aspects of MCH have so far been little exploited by WHO. A few subjects which suggest themselves are the differences in growth and development patterns of children in areas with different child feeding and rearing

statistical nature that have a bearing on the progress of nursing, but of more importance are certain events with significant implications which more clearly mark the progress of nursing in the past decade.

Nurses Recognized As Essential

Of a tangible nature is the establishment of the World Health Organization and the technical assistance programs of the United States Government and of the Colombo Plan, to mention a few. These are things we see and read about and provide funds for. There is, however, one tremendously important but intangible event that, in my opinion, constitutes the most significant development in nursing. This needed no treaties, no funds, no agreements—it simply happened because it was inevitable. It is the recognition of the essentiality of nursing in providing health services for the people of the world. To be sure, we have always said that nurses were needed in hospitals, in public health programs, in industry, and in other areas. But only recently has the nurse been recognized as essential in the development of adequate health services if the peoples of the world are to be served adequately. There is considerable evidence to support this now accepted fact.

We know that the development of nursing in any country is limited to a great extent by the state of development of that nation's medicine and public health. However, as the World Health Organization Expert Committee on Nursing has stated, in countries where medicine is highly developed and nursing is not, the health status of the people does not reflect the advanced stage of medicine. Nursing, therefore, becomes essential to the vitalization of any health program.

In 1948, at the meetings of the First World Health Assembly, only one country included a nurse as a member of its delegation. Eight years later at meetings of the same agency, 20 countries sent a nurse as a member of the delegation. This is a momentous change and a challenge to nursing.

In 1949 the United States included a nurse as one of the three advisers to the United States

delegation to the meetings of the United Nations Commission on the Status of Women, held in Beirut, Lebanon. Since those meetings, whenever the agenda of the United Nations Commission on the Status of Women included items on the health of mothers and children, either a nurse has been a member of the United States delegation or a nurse's advice on agenda items was sought. The United Nations Commission on the Status of Women has also given support to nursing in member countries.

At the Ninth World Health Assembly in 1957 the theme of the technical discussions was "Nurses: Their Education and Their Role in the Health Programs." Preliminary reports on which these discussions were based were received from 33 countries, and all members of each country's health team participated in the preparation of the papers and in the discussions. From the many significant statements in the final report of these discussions, one or two will suffice as evidence of the essential role of the nurse. One statement says that "all countries recognize the need for post-basic study for graduate nurses so that they are prepared to hold positions as nursing administrators, supervisors of nursing services, teachers in schools of nursing and for certain clinical specialties." In other words, it is recognized that nurses can and must assume the responsibilities for nursing.

Another entire section deals with conditions which limit the effectiveness of nursing service in the health program. It is significant that the member countries recognized the need to study those conditions that detract from the concept of the essentiality of nurses and those that can be changed.

In May 1957 the International Council of Nurses held its Eleventh Quadrennial Congress in Rome. This is really not an unusual event, since these congresses are usually held every 4 years. But it is important that 9 new countries were admitted to full membership and 5 countries were admitted as associate members. Thus nursing representatives of 51 countries gathered to share experiences and to speak for nursing. At this congress the report of the WHO technical discussions of 1957 was cited constantly as an authoritative source, and many

NURSING

AROUND THE WORLD

VIRGINIA ARNOLD, R.N.

PEOPLES throughout the world are waking up to the fact that good health is their right, and their demands for wider and improved health services have shaken us out of our complacency and have forced changes in outmoded systems of health services. Nursing has been caught up, too, in this demand for better care. Much of the progress in nursing

Miss Arnold is assistant director for medical education and public health for the Rockefeller Foundation, New York City. This article is based on an address given at the 1957 meeting of the American Public Health Association, November 14.

in the past 10 years has been effected by the nurses themselves, but no small part is due to the demands and the push from society.

How can the progress of nursing be demonstrated and evaluated? Would it give you a true picture if I listed the newly established schools of nursing in the Middle East, the Far East, and in Latin America? Would it help you to know that many more girls are entering nursing than at any other time in history? Would the picture be clearer if you knew that more nurses' associations have become members of the International Council of Nurses? I could describe other items of a more or less

The baby helps train Greek student nurses to become "substitute mothers."

with Syrian nurses in the key positions. And in Egypt, a school of nursing has been established in the University of Alexandria.

The countries in the Far East are also moving ahead in the development of nursing. Taiwan has started a university school. Japan is pushing vigorously ahead. India is leading the way in many respects. And the gentle Vietnamese, in whose country nursing education was nothing more than an apprenticeship a few years ago, are increasing their 2-year course to 3 years, and Vietnamese nurses are directors of two branches of the National School of Nursing located in Saigon and Hue.

Developing Professional Role

If we consider regions rather than individual countries, we can certainly say that Latin America has advanced more rapidly than any other region of the world. Last year, the Brazilian nurses realized that they knew too little

about their professional situation and felt that nursing was at a stage of development where they must decide which road it would follow. So the Brazilian Nurses' Association undertook a survey of the nursing resources of the entire country. This important survey will be completed in June 1958. Considerable useful and revealing data have come from this survey already. Other countries are beginning to look at their own nursing resources more carefully as a result of the Brazilian study.

Another significant mark of progress in Latin America is the thorough scrutiny of curriculums which is now going on in many schools of nursing. Formerly, the better schools quite clearly reflected British or American patterns and influences. But in recent years the conviction is growing that these are not good enough because they do not prepare the nurses adequately for the health problems peculiar to their own areas. As an example, courses in teaching and supervision are being introduced in the third year

Visiting nurse aide explains simple rules of health to a family in Brazil.

were the reports of changes based on the recommendations in the WHO report.

Growing Responsibilities

And, with regard to the matter of nurses' speaking for themselves, in many countries a nurse has been appointed to a position of responsibility in the Ministry of Health. In two countries, Sweden and Finland, nurses are members of parliament.

Let's look at the Middle East for a moment and note some of the changes in that part of the world.

The School of Nursing of the American University of Beirut inaugurated a postgraduate course in public health nursing in 1954. The graduates of this course have already influenced public health nursing practices in the surrounding Arab countries. But, in Iran in 1951 nursing was in a sad state. The quality of nursing education was poor; services were lacking or

inadequate; and the midwife enjoyed a prestige far beyond that of the nurse. In the past 2 years, there have been some notable changes, demonstrated most dramatically by the shift in status of the midwife vis-a-vis the nurse. Now midwives are asking for the opportunity to obtain their basic nursing training so that they can compete more favorably with nurses and nurse-midwives. In 1956, Iran held its first nationwide conference on nursing, inviting to it internationally known leaders in nursing. At this conference, for the first time, the Iranian nurses took a good look at their professional position and, as a result, drew up plans for legislation, educational standards, and organization of nursing services.

In Jordan, within a period of 6 months, the right to vote was granted to certain women; the first national conference on nursing was held, and the Jordanian Nurses' Association was formed. In Damascus, the school of nursing in the university is moving ahead steadily,

Lest I mistakenly leave you with the impression that nurses alone have brought about all these changes, I shall mention a few other forces and factors that have played an important role. Among these are the spread of the emancipation of women, the expanded educational opportunities for girls, the number of girls receiving advanced schooling, the creation of new nations with their developing health services, the tremendous cultural and sociological changes in some areas of the world, the great ease of com-

munication which facilitates the exchange of ideas, the dramatic technical and scientific advances, and the pressures brought to bear by the masses for improved health services. In this complex and changing world, particularly in the East, women today in different degrees are playing a vital part, no longer content to be merely bystanders and recipients of the benefits of change, but demanding that they be allowed to work creatively in their own environment to help form a new society.

Perinatal Mortality Conference

If avoidable perinatal mortality is to be reduced, a new philosophy and a new approach to the education of doctors, nurses, and patients are needed. This was the consensus of a conference followup of the New York Academy of Medicine's 1955 study of mortality among infants from the 20th week of gestation through the 6th day after birth.

The conference at the Academy on October 29, 1957, was sponsored by official and voluntary agencies and representatives of the medical profession. Specialists in obstetrics, pathology, anesthesiology, nursing, hospital administration, social work, preventive medicine, and public health education participated.

Group discussions of questions raised by the study of 955 perinatal deaths in New York City led to recommendations for improving maternity care and reducing infant deaths.

Prematurity, the cause of two-thirds of perinatal mortality, could be lowered by strengthening prenatal care; prescribing nutritional supplements according to the mother's needs, just as medication is prescribed; doing more social case work among expectant mothers; avoiding meddlesome obstetrics and elective inductions of labor; and prohibiting active physical work for women with small heart volume and low hemoglobin. The conferees

also pointed out that prematurity is expensive; in a municipal hospital the care of a premature baby costs \$360, a full-term infant, \$100.

The specialists listed what hospitals and maternity clinics can do to reduce perinatal mortality.

They recommended that hospitals should emphasize the needs of people as much as the acquisition of skills in teaching interns and house physicians; provide 24-hour supervision with the supervisors aware of the background of each patient in labor; encourage mothers, once they return home, to telephone for advice; assign a staff member to answer their calls; and discuss current perinatal mortality regularly at staff meetings.

They also said that hospital maternity clinics should be encouraged to use more social workers and nurses trained in midwifery; set up appointments to reduce patients' waiting time, and use waiting time in the clinic for prenatal education.

The conferees further suggested that information about childbearing be made part of every young person's education and urged more research in habitual abortion, endocrine imbalance, physiology of the uterus, and physiology and function of the placenta.

Giving typhoid immunizations is part of this student's course in public health nursing at American University of Beirut, Lebanon.

because the graduates, however young and inexperienced, are called on to assume positions of responsibility in teaching and supervision. This situation will probably remain unchanged for some time to come.

In many countries, midwifery, including maternal and child health, and basic nursing are still separate professions. This concept is now changing with the recognition of the importance of midwifery and maternal and child care as a part of the education of the nurse.

Another significant improvement is reflected in the marked increase in the number of articles on nursing written by Latin American nurses, and in their growing interest in the writing of nursing textbooks. Such textbooks, made available in Spanish for all nurses, will release them from dependence on translations of Eng-

lish and American textbooks, which may or may not apply to their situations.

The nursing profession is becoming interested and actively engaged in various aspects of research. Last year, the Florence Nightingale International Foundation held a 2-week seminar on research at Sévres, France, the first of its kind. Representatives of 20 countries participated, each reporting on some special study going on in her own land.

The International Labor Organization, a specialized agency of the United Nations, has undertaken a worldwide study of the employment and working conditions of nurses. The ILO states that the objective of the study is "to obtain the fullest possible information on the social and economic status of nurses throughout the world."

training courses for midwife aides. It is a well-conceived program which is gradually expanding to serve the needs of the people and to become a training center for the area.

The men's hospital is a 60-bed facility for which the provincial health officer is gradually acquiring improved equipment. Some of the new equipment has been acquired from the United Nations Children's Fund. In the outpatient department, emphasis is placed on preventive medicine, particularly venereal disease control.

Venereal disease rates of prevalence have been comparatively low in Afghanistan. Nevertheless a program to control these diseases was one of the first modern public health activities to be undertaken by the government. In Kandahar it is under the direction of an Afghan physician who received training at Johns Hopkins University under a WHO fellowship. Treatment schedules are modern, utilizing penicillin procaine with aluminum monostearate, and the control program includes case-holding activities, mass blood testing, contact tracing, and education.

Associated with the two hospitals in Kandahar is a well-equipped X-ray institute under the direction of an alert, energetic doctor. It contains equipment also for taking electrocardiograms and measuring basal metabolism.

To Kabul

From Kandahar to Kabul (pronunciation rhymes with gobble), we flew over valleys between rugged mountains. In the valleys are occasional patches of irrigated fields and a few towns. One of the towns is Ghazni, which many centuries ago was the cultural center of this part of the world. We also saw evidence of many of the underground channels which in Afghanistan are called *karez* and in Iran, *ghanats*. From the air, they look like rows of doughnuts. Each "doughnut" represents a place where the dirt from the underground channel has been brought to the surface. The *karez* are the means by which ground water from the bases of the hills and mountains is channeled with a minimum of evaporation to the fields and villages where it is used.

After the bumpy trip over the mountains,

we arrived in Kabul, which is another city undergoing the process of modernization. The most obvious evidence of this is the streets, which a few years ago were bumpy and rutted and which now the government, with Russian assistance, is paving.

Here, as in Kandahar, the air of change is reflected in the medical and public health institutions and facilities. Under the guidance of a Minister of Health who obtained his medical and public health education in American schools, and with the assistance of WHO and UNICEF, the government is emphasizing solution of the basic problems of sanitation, hygiene, and preventive medicine.

The People

The inhabitants of Afghanistan are a mixture of people of Mongolian, Aryan, and Semitic origins. The so-called "true" Afghans speak Pashto (pronounced pushtoo). The men of this group are usually tall and broad shouldered with straight noses, regular features, and rather dark complexions, although some are fair, claiming descent from the Greek legions of Alexander and the ancient tribes of Israel. The group belongs to the Pathan tribes and is dominant ethnically. One of these, the Durani tribe, numbering less than 1¼ million people, has been the ruling faction for the last 200 years.

In a broad band along the Russian border and the Oxus River are the Turkomans of Mongolotartar origin, differing from the rest of the population by their Turkish dialect, dress, and the shape of the tents used by their nomadic members. They are herdsman and breeders of karakul sheep. South of the Turkomans, in the center of the country, are found the Hazaris, of Mongolian origin, descendants of Genghis Khan's followers. They speak Persian and related dialects.

In a small pocket in the east central area are the Uzbeks, a fair-skinned people with Mongoloid features belonging to the Turki-speaking tribes. Along the Iranian border are isolated groups of Tajeks, who are racially Persians but who resemble the "true" Afghans. They tend more to engage in industrial pursuits than do other Afghans, those living in towns forming

Afghanistan

charts health goals

GLENN S. USHER, M.D., M.P.H.

Afghanistan is a newly emerging nation of the free world which in recent years has accelerated the development of its resources. The government recognizes that its greatest resource is its people, and is striving to improve their health and well being.

In the spring of 1957 the Minister of Health of Afghanistan requested the International Cooperation Administration to provide consultation relative to the expansion of the country's health program with ICA's assistance. Accordingly, at ICA's request I visited Afghanistan in July and August of that year.

FROM KARACHI, Pakistan, to Kandahar, Afghanistan, the plane flies over a vast expanse of eroded hills almost devoid of human habitation. Then suddenly an oasis of irrigated fields appears below. This is Kandahar, the first stop in Afghanistan.

Kandahar gives the impression of being a city of unfinished buildings. One drives through long rows of them in various stages of construction, mute evidence of plans afoot to make Kandahar a major air terminus.

In the hospitals also there is an air of anticipated change. There are 2, 1 for men and 1

for women. While a new women's hospital is being constructed, female patients occupy the residence of a king who ruled 100 years ago. As it is a relatively new thing here for women to seek hospitalization, only a few beds for in-patients are provided in this temporary facility.

For the present, the health services of Afghanistan emphasize preventive medicine and maternal and child health activities. With the help of a physician and two nurses provided by the World Health Organization (only the two nurses remain), the Afghan provincial medical officer and his staff have organized prenatal and postnatal clinics, pediatric and well-baby clinics, mothers' demonstration classes, a domiciliary midwifery program, and

Dr. Usher is special assistant for medical activities, Communicable Disease Center, Public Health Service. At the time this paper was written, he was chief of the Program Development Branch of the Division of International Health, Public Health Service. Some of the background information for the article was compiled by Jane H. Priest, analyst in the Program Development Branch.

Kabul, 15 provincial, and 15 small district hospitals, with a total capacity of some 1,400 beds (1). Separate hospitals are maintained for men and for women. Under the government's 5-year plan, funds have been allocated with which to build additional hospitals and to provide better facilities and modern equipment for the existing ones. In this building program, emphasis will be placed on providing more hospital beds for women in order to bring their facilities up to a par with those for men.

Only 249 physicians have been graduated from the Faculty of Medicine since its founding in 1932. Probably not many more than 200 are practicing at the present time, and there are about 15 or 20 foreign physicians in the country.

A limiting factor in relation to medical education, as well as all other forms of higher education in Afghanistan, is the small number of students who are graduating each year from the secondary schools. However, the number is increasing year by year, and in addition just this past year the government has decided to allocate a larger number of them to the Faculty of Medicine. Whereas in recent years the number of admissions to the study of medicine has been about 35 or 40, it was expected at the time of this visit that about 100 would be admitted this year. This poses a serious problem to the Faculty in providing the facilities and instructors to teach that number of students. In its 5-year plan the government has allocated substantial sums of money to provide the facilities and to upgrade the teaching hospitals.

The training of nurses is also the responsibility of the Faculty of Medicine, and in this area too it is faced with a serious problem. Up to the present time few nurses have been trained. They are mostly male nurses. The Faculty has asked WHO for help, and a 5-year plan has been developed which calls for a rapid expansion in nurse training.

The training of midwives, on the other hand, is under the jurisdiction of the Ministry of Health. For this purpose it uses the recently upgraded maternity hospital in Kabul. Assistance in providing better equipment was given by UNICEF, and services were greatly improved with the assistance of WHO personnel, especially by Dr. Gade, a Danish woman physician who won the hearts of the Afghan

personnel with whom she worked. She established the midwifery school in a large building constructed on the grounds by the government. The school is now under the direction of a princess of the royal family.

Public Health Activities

In addition to bringing typhus fever under control, the government is making good progress in eradicating malaria and in establishing maternal and child health facilities. A start has been made on tuberculosis and venereal disease control and in the improvement of sanitation in a few limited areas of the country.

The Faculty of Medicine is expanding its training program for both male and female nurses, and the Ministry of Health is expanding its training programs in public health for physicians, public health nurses, midwives, sanitarians, laboratory personnel, and statistical personnel. The Ministry of Health, with the assistance of WHO, has recently established a school for sanitarians which is being expanded.

Public Health Institute

To develop and coordinate these various training activities the Ministry of Health is in the process of establishing an Institute of Public Health. In addition to the development and coordination of training activities the institute will administer the public health laboratory, the Ministry's health statistics activities, and a new health education department. It will establish a public health library, and it will conduct epidemiological and nutritional studies and surveys.

Out of these activities the Minister feels that there will be derived the means for more effective evaluation of public health programs and for the intelligent establishment of program priorities realistically related to disease prevalence, the socioeconomic condition of the people, and the available resources. It is an ambitious undertaking for a country in the early stages of its economic development but one which should make a substantial contribution to the effective execution of the country's public health programs.

most of the Afghan middle and upper-middle class.

The nomadic herders, known as *Kochis*, or choochies, probably constitute about 25 percent of Afghanistan's population of 12 million. Many travel from their summer ranges along the Iranian border and the Hari River Valley to Pakistan for the cold months, often crossing the Khyber Pass at the rate of 10,000 a day at the height of the migration (1-3).

Living Conditions

Even in the cities the scarcity and high cost of lumber prohibits the use of wooden houses. Plastered mud brick, baked brick, and stone are the materials used. Many of the poorer homes have domed roofs to avoid the necessity of using wood to support a flat roof. The flat roofs are covered with sun-dried mud which sheds water quite well in a heavy rain but which in a slow rain or sleet often leaks. The better homes in the cities are rather well constructed and have tile floors, but the poorer homes usually have floors which are not impervious to water.

There is much overcrowding with consequent hazard of transmission of communicable diseases. Furthermore, in the kitchens one seldom finds the sinks, tables, and utensils which would facilitate the sanitary handling of food (1).

Water Supplies and Sanitation

Kabul and some of the larger towns have water supplies with community taps. The government is taking steps to improve these supplies and make them safer. In fact, the city of Kabul is drawing up plans for a modern water supply system. In most of Afghanistan not only agriculture but the gardens and trees in the cities and villages depend upon irrigation. The irrigation ditches are subject to pollution from many sources, and it is from these that some of the people derive their water supplies for domestic use. Also, vendors use this water to freshen their vegetables. (Another great hazard to the sanitary quality of vegetables is the use of night soil as fertilizer.)

In many of the small towns and rural areas,

well water is used. The Ministry of Health is planning a large well-drilling program to increase the availability of this source of supply and is preparing sanitarians to supervise construction and to teach sanitary maintenance of the wells.

These sanitarians will also be utilized to help improve general conditions of sanitation and hygiene, and it is expected that their effectiveness will be augmented by an aggressive health education program which the Ministry is planning.

Health Conditions

The Ministry of Health has established a health statistics section and, with the help of the World Health Organization, is taking steps to improve the collection and analysis of statistics. As things stand now, however, there is very little factual material on which to base estimates as to length of life or the prevalence of disease. Estimates of life expectancy in Afghanistan range from 20 to 40 years.

Malaria, tuberculosis, intestinal diseases, and poor nutrition are said to be the principal preventable health problems, but a nationwide malaria control program, assisted by WHO and UNICEF, is rapidly bringing malaria under control. Typhoid and paratyphoid fever and the dysenteries are endemic with epidemic outbreaks. Until recently, typhus fever epidemics occurred regularly, but now they have largely been brought under control. In 1956 there was not a single confirmed case of typhus fever in the country. Infestation with parasites is almost universal in children, and diarrheal diseases are extremely common. Trachoma and other eye disorders are prevalent, at least in some areas. The prevalence of venereal diseases, on the other hand, appears to be relatively low. Any estimate of the infant mortality rate would be little better than a guess, but it is undoubtedly well over 100 per 1,000 live births (1, 3-5).

Medical Care Facilities

Most medical institutions in this country are supported by the government, and treatment is provided free. There are 35 hospitals, 5 in

International Population Movements as Aids to Communicable Disease Control

CLARENCE A. SMITH, M.D., JOHANNES STUART, Ph.D.,
and WILLIAM C. WATSON, Jr.

POPULATION movements have always been viewed as a real or potential hazard in the spread of communicable disease. In the Crusades, the internecine conflicts of the Renaissance, and the conquests which brought the Americas into the orbit of European culture, disease was always one of the horsemen riding side by side with the soldier, the merchant, and the priest. The traveler's course might be traced by the implantation of disease as well as by the growing weeds whose seeds had dropped from his saddlebags.

It is only in recent years, and even then with little real appreciation of its inherent logic and potential strength, that public health workers have taken advantage of population movements and used them as a positive force for health by combining a few simple ingredients of border inspection, quarantine, treatment, and control epidemiology.

While several rudimentary examples of this approach in regard to mobile populations have emerged from the operation of the venereal disease control program of the United States, no example existed prior to 1956 in which use was made of an international population movement

that would apply all of the basic elements of venereal disease control for the benefit of two countries.

It was therefore a program of new stature which the national health agencies of Mexico and the United States undertook in 1956 when they decided to weld together the elements of a complete international control program and apply it to Mexican migrant laborers coming into the United States during the growing and harvesting season.

It should be clearly understood that such synthesis cannot be affected at will. It is based on mutual respect and understanding between the two nations as well as upon a number of preconditions, including facility and speed in diagnosis and treatment, the existence of a contact-eliciting and contact-tracing mechanism, and the availability of forces which can be mobilized to accomplish diagnosis, treatment, and contact investigation. Even in 1956 when jet planes hurtled through the air at speeds far exceeding sound and the mysteries of orbital space had become the commonplace of newspaper headlines, these factors were not entirely adequate to cope with all aspects of the combined programs; they were present in sufficient degree, nevertheless, to merit the sizable demonstration test which we describe.

More than 400,000 Mexican agricultural workers enter the United States each year to work in our fields at the times when there is an urgent seasonal demand for labor. Physical examinations are given these workers by the Public Health Service Division of Foreign Quarantine, both at the recruitment centers in

The authors are all with the Public Health Service. Dr. Smith serves as deputy chief of the Communicable Disease Center, Dr. Stuart, public health advisor in the Office of the Surgeon General, and Mr. Watson, public health advisor in the Venereal Disease Branch of the Center. By special arrangement, the article appears simultaneously, in substantially the same form, in the Boletín de la Oficina Sanitaria Panamericana.

The Helmund Valley

To go from Kabul to Lashkar Gah, we flew back to Kandahar and then traveled 90 miles west over a gravel road, one of the best in Afghanistan. Both Kandahar and Lashkar Gah are in an area which in recent geologic time was probably part of a vast lake without an outlet. The area still has no outlet for the streams and rivers which flow into and through it. They flow into a great salty depression in the southwest portion of the area and there the water which does not sink into the ground evaporates.

Lashkar Gah, a new city located on the Helmund River, is the headquarters of a large irrigation and land development project administered by the Helmund Valley Authority, which is similar in some respects to the Tennessee Valley Authority. The project is being used for the settlement of large numbers of people from the nomadic tribes.

Lashkar Gah is being built for the specific purpose of providing headquarters for HVA and for the government of Girishk Province. It is expected that the provincial government will be moved there soon. The city derives its name from a city which was once a flourishing military cantonment in an ancient Afghan empire, but which is marked today only by hulking ruins nearby. In the neighborhood are also ruins of a castle which was 8 stories high and covered some 2 or 3 acres of ground.

The city is being built according to plan, with well laid-out streets, well designed and constructed houses, a good water supply, and a sewage-disposal system. The foundations are being laid for a 30-bed demonstration health center and training school for health personnel, which will be modern in design and equipment. With the assistance of the International Cooperation Administration, the health center will be the central facility for a network of subsidiary health centers in Girishk Province, which forms the major part of the area under the jurisdiction of HVA. It is planned that from these health centers not only the new settlers but the old inhabitants of the area also will receive the benefits of modern medicine and

public health and the present-day teachings of hygiene and sanitation (2, 3).

Summary

Substantial progress has been made in establishing the medical and public health institutions and organizations needed in Afghanistan. Training of essential personnel is necessarily slow because of the scarcity of people with the prerequisite educational qualifications, but this problem is being alleviated as the educational system expands.

Progress is being made also in combating some of the country's most serious preventable diseases, notably malaria and typhus fever, and in developing maternal and child health activities, but much remains to be done in the *entire field of public health and sanitation*. Implementation of the plans of the Ministry of Health for the development of its new Institute of Public Health should contribute materially to the improvement of health facilities and programs.

Another interesting development which is planned for the near future is the establishment of a public health program in the Helmund Valley which will provide health services for nomads who are being settled on newly irrigated land and will at the same time provide a demonstration of the application of public health methods and an area for the training of public health personnel.

Pursuant to our agreement, and in cooperation with the U. S. Department of Labor, two of the reception centers—El Paso, Tex., and El Centro, Calif.—were chosen for the assignment of such teams over the period August 16 to October 12, 1956. This period covers the great fall harvesting season when the migrant movement swells to a peak. During that period 115,506 Mexican workers were blood tested; 9,240 were found reactive to a serologic test for syphilis; 7,098 were given treatment in the United States; 1,532 notifications were sent to Mexican health departments on workers not found prior to their return to Mexico; and 7,004 marital contact reports on the wives of workers with a positive test for syphilis were sent to Mexican health departments. All in all, then, the control aspect of this program concerned itself with 16,244 syphilis suspects, comprising the 9,240 men who were positive reactors and the 7,004 women who were married to positive reactors.

Who were these people, and what happened to them? Table 1 and the chart show the distribution of the male workers and states from which they came. Almost 80 percent of all the migrants tested at El Centro and El Paso came from the six states of Chihuahua, Durango, Guanajuato, Jalisco, Michoacan, and Zacatecas, but the rate of positivity for this group was somewhat lower than average. Certain other areas with a lesser flow of migrants, such as Baja California (Norte), Distrito Federal, Guerrero, and Nayarit, contributed markedly higher than average rates of positivity. Although these states vary widely in the known prevalence of pinta, no attempt was made to evaluate the role which each of these diseases played in the total numbers of serologically positive tests.

Marquez, Rein, and Arias, in reporting findings of the study of pinta in Mexico carried out by the Mexican Ministry of Health during 1929-31, indicate that those states affected were Guerrero, Oaxaca, Mexico, Chiapas, Michoacan, Puebla, Tabasco, Morelos, Nayarit, Veracruz, and the highest prevalence was found in Guerrero where approximately 20 percent of the population is affected.

The Mexican Ministry of Health had requested us to prepare the tabulations given in table 1 since this would give them a helpful

cross section analysis of treponematoses in the areas from which migration came. The data do not, of course, reflect internal variations within the states concerned but, since the majority of the contract workers were rural and since the migratory populations have other identifying characteristics, the information contained in the table should be of considerable use to control programs in the areas concerned. The table provides a current index to the extent of the problem among the group tested.

But, however important it may be to define the extent of a problem, it is much more important to do something about it. Herein lay a great difficulty. We knew that the stay of the Mexican workers in the reception centers was usually for only a few hours. It was something of a problem even to collect a blood speci-

men on all comers during those few hours because the centers were set up to process as many as 4,000 men per day, and our teams experienced a number of days when the flow was well over 3,000. Even writing a laboratory report form on each man was out of the question, especially since most of our team members did not speak Spanish. So we decided to microfilm the workers' Labor Department identification forms, an important factor in the control operation because it also contained the name, re-

Mexico and the reception centers on the American side of the border. These examinations serve to detect most of the clinically evident venereal disease. However, in the absence of a blood-testing program, syphilitic workers without clinical symptoms at the time of admission have gone undetected. Mexican and United States health workers have repeatedly explored means of using the opportunity presented by these population movements to develop a syphilis control program benefiting both countries.

Mass Blood Testing Begun

Because of difficulties of organization and finance, no substantial combined activities were undertaken until 1956, when it was informally

arranged between the two Federal health agencies that as many of the migrants as possible would be blood tested in Mexico and that the Public Health Service would assign syphilis control teams to at least some of the five reception centers through which Mexican agricultural workers pass to be processed and assigned to the growers who use their services.

The United States testing teams reported that an occasional worker volunteered evidence of a recent serologic test for syphilis. It was, however, impossible for these teams, handling a high volume of workers with whom they had communication difficulties, to determine how many had been blood tested in Mexico. It is the activities of the United States teams that we report in the following paragraphs.

In the States of the Pacific Coast we had a strong case-finding ally in the Continental Casualty Company, the insurance firm which provides medical care for braceros on the west coast. They voluntarily proposed that their officials in California arrange, with the aid of the growers' association and farmers, to locate each serologically positive Mexican worker and bring him in to the office of their local physician for diagnosis and treatment. We accepted this offer with great alacrity, although we assured the company that their task would not be an easy one.

Nor was it accomplished without some substantial difficulties. Some few growers' associations at the peak of their seasonal work were at first apathetic or even hostile. Some physi-

cians found themselves so burdened with the other medical problems of braceros that they could not give effective service to the syphilis suspects, so that the Public Health Service had to send in help. But the great bulk of seropositive men were finally found and treated.

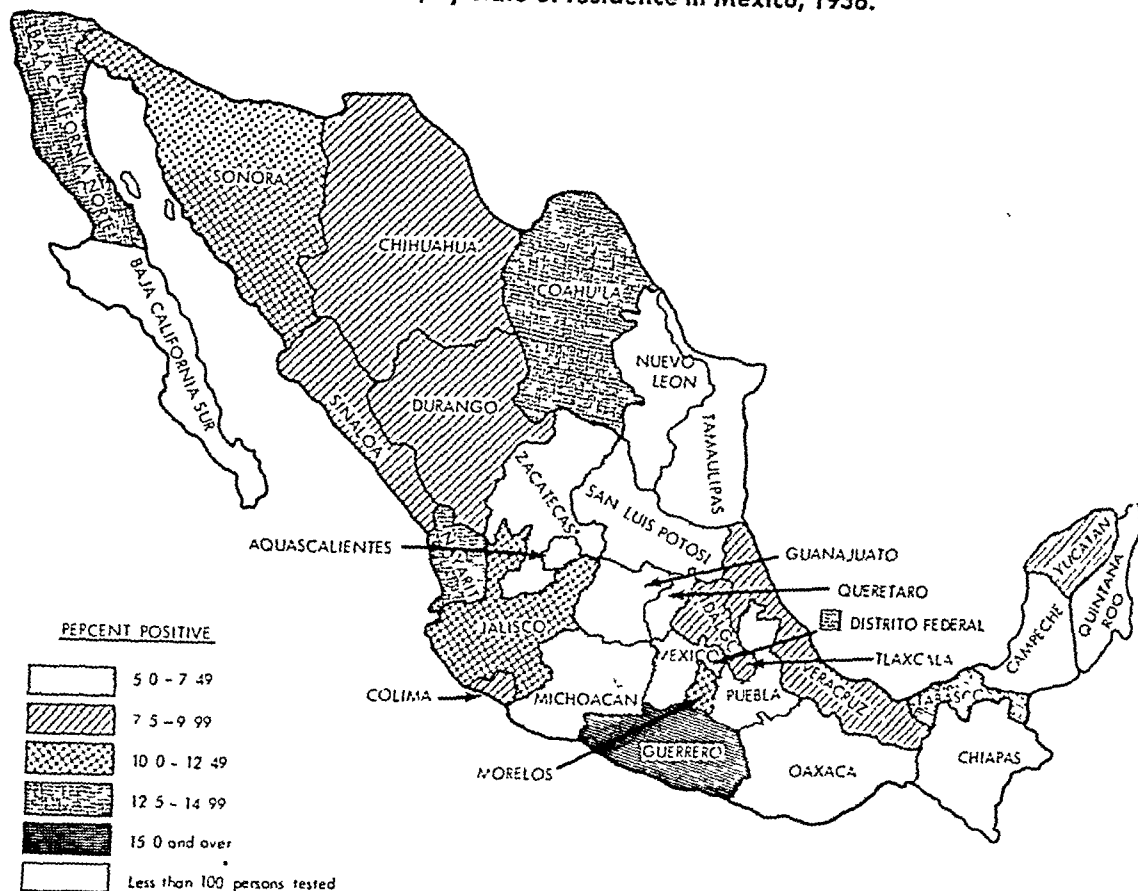

In the other States—chiefly Texas, New Mexico, and Arizona—case finding was done by regularly employed investigators working in the State venereal disease program. They were focused on the areas receiving braceros for the period of need. In New Mexico and Arizona, public clinics provided diagnosis and treatment. In Texas, medical service was obtained in large part by contract with private physicians.

lationship, and address of his nearest-of-kin, usually his wife.

On this Labor Department form we stamped the number of the worker's blood tube. Then, after the name and address of the grower to whom he had been assigned was entered on the form, we microfilmed the entire document. We therefore had in our possession on one document a complete record of where we could locate both the man and his wife—a document obtained at a cost of seconds per person tested.

Case Finding Expedited

We knew that finding these workers after they had left the reception centers would not be easy. Back in 1951 we had experienced bitter failure in our first attempt to do this. In that year we tested some 11,000 Mexican braceros, sent their blood specimens to the Public Health Service Venereal Disease Research Laboratory

in Atlanta, and the positive reports to the State health department concerned. Because of the time lapse involved, most of the persons with positive blood were never found: they had moved from the farm of their original assignment.

This time we were prepared to deal more expeditiously with the laboratory phase of the program. With the active and energetic cooperation of the State health department laboratories of Arizona and Texas, serologic reports reached the reception center within 24 hours after blood specimens were taken. Blood was flown from the center to the laboratory in the afternoon, analyzed the following morning, and reports returned to the center on the same day. Suspect reports prepared by the center on all individuals with a seropositive test for syphilis might therefore reach the destination of the bracero very shortly after his arrival on the farm of his first work assignment.

In the States of the Pacific Coast we had a strong case-finding ally in the Continental Casualty Company, the insurance firm which provides medical care for braceros on the west coast. They voluntarily proposed that their officials in California arrange, with the aid of the growers' association and farmers, to locate each serologically positive Mexican worker and bring him in to the office of their local physician for diagnosis and treatment. We accepted this offer with great alacrity, although we assured the company that their task would not be an easy one.

Blood was flown from the center to the laboratory in the afternoon, analyzed the following morning, and reports returned to the center on the same day. Suspect reports prepared by the center on all individuals with a seropositive test for syphilis might therefore reach the destination of the bracero very shortly after his arrival on the farm of his first work assignment.

their cost. Venereal disease control programs in the United States, as one aspect of their effectiveness, have always been mounted on the firm base of economical operation. This program was no exception, as can be seen from table 4. Total cost of blood testing was held to less than 60 cents per person, followup and treatment to an average cost of \$3.39 per person, and the unit cost per suspect to 19 cents per report sent.

Conclusions

This program demonstrates several novel combinations: the utilization of a quarantine procedure as a basis for a full-scale venereal disease case-finding, treatment, and contact investigation program, as well as for depiction of the geographic distribution of another country's problem; the practical elimination of distance in laboratory functioning; the use of microfilm as a technique for venereal disease control; and the backing of an insurance company in health control operations.

Attention to operational novelties, however, emphasizes process over concept: the concept that the quarantine procedure shares with other testing devices the powerful potential of a case-finding tool.

Quarantine will continue to maintain the devices which protect against the hazards of disease importation. But it also may become—possibly for chronic as well as communicable disease—one of the screening devices which in the future will share with other health services the responsibility and the reward for alerting the individual and the community—the community of nations included—to the presence of disease and the needs and methods for its control.

NIH Board of Scientific Counselors

A panel of six non-Federal scientists has been selected to comprise the Board of Scientific Counselors, established in February 1958 by the Public Health Service to review, discuss, and make recommendations on research in laboratories of the National Institute of Neurological Diseases and Blindness. The board held its first meeting in Bethesda, Md., February 20 and 21, 1958.

Chairman of the board is Dr. Hallowell Davis, director of research at the Central Institute of the Deaf, St. Louis. He will serve 4 years.

Appointed for 3-year terms are Dr. Howard J. Curtis, chairman, biological division, Brookhaven Laboratory, Upton, N. Y., and Dr. A. Earl Walker, professor of neurosurgery, the Johns Hopkins University.

The 2-year term members are Dr. Raymond Adams, chief of neurological services, Massachusetts General Hospital, Boston; Dr. Algernon B. Reese, clinical professor of ophthalmology, Columbia University College of Physicians and Surgeons; and Dr. Roger J. Rossiter, head of the department of biochemistry, University of Western Ontario, London, Canada.

actors were treated (table 2). Of the 2,119 not located, suspect report forms were sent on 1,532, after the crop season was over. Information on the suspect was transmitted on the recently instituted multilingual form developed by the Pan American Sanitary Bureau and now available for use by all nations of the Americas in the international reporting of venereal disease contacts and suspects. This form, sent to the Mexican state health department of jurisdiction, advised in Spanish that the person named had been tested in the United States, that the result of this test was positive, and that he had returned to Mexico before diagnosis could be made and treatment instituted.

This completed our work on the 9,240 braceros whose blood tests were positive. Its overall efficiency was 77 percent, even without accounting for the men who might subsequently have been located in Mexico. This is a pretty fair degree of case-finding efficiency for any group of syphilis suspects, but is phenomenal in relation to so highly mobile a foreign language group.

As has been indicated earlier, we reported to Mexico a total of 7,004 women who were marital partners of braceros with a positive test for syphilis. The reports on these wives were also sent on the Pan American Sanitary Bureau form. Each of these, too, carried an individual communication in Spanish advising the recipient health department that the person named in the form was a familial contact of a serologically positive Mexican worker currently in the United States. It further requested that the Public Health Service be notified as to the results of investigation.

Relatively few replies were received indicating what action had been taken (table 3). This is not particularly surprising. In the first place, our experience in the United States indicates that there is a curious reluctance on the part of several State health departments to report a disposition on a contact report received from out of State. Since reporting to another country involves the mental bridging of an even larger gap, we can readily appreciate how much good case finding may have been accomplished through the use of these forms without our obtaining disposition reports.

We were also aware that a number of the addresses of wives which we used were incorrect

or insufficient. Even though these addresses may be of great importance to the workers in the case of illness or death; poor communications, poor understanding, and possibly other factors work against their accuracy.

Finally, the Pan American Sanitary Bureau form and the contact investigation procedure is relatively new to many Mexican health departments, particularly those of the rural areas from which most of the braceros come.

In spite of the low rate of return on disposition, it is of interest that almost a fifth of the cases reported as having been examined were brought or returned to treatment, indicating the relatively rich epidemiological vein which this reporting method makes available. If 17.5 percent of all the wife suspects were in need of treatment, the information contained in the 7,004 suspect reports might have led to the treatment of some 1,250 women with syphilis in Mexico.

Many desirable public health programs are relatively or absolutely impractical because of

Samples taken in 1955 indicate that most atmospheric particles likely to reach the lungs had a radioactivity of less than 5 μc ., but the radioactivity of single particles was as high as 500 μc . The average concentration of beta activity was about 5 μc . per cubic meter of air.

Radioactive Particles in the Atmosphere at Cincinnati, Ohio

R. LOUIS BRADSHAW, M.S.E.E., and LLOYD R. SETTER, Ph.D.

THE RADIOACTIVITY of air particles in samples collected in 20 to 30 municipalities in the National Air Sampling Network, established in 1953, indicated a thousandfold or more increase in beta radioactivity immediately following known tests of nuclear weapons. It was suspected that substantial amounts of the total radioactivity might be associated with discrete particles which might find their way into the respiratory tract of man. To determine the distribution of radioactivity in atmospheric particulate matter, a study was made of air samples collected at the Robert A. Taft Sanitary Engineering Center, Cincinnati, Ohio, during the winter and spring of 1955.

Sampling Apparatus

The particles in air samples were separated into primary and secondary fractions by a cyclone separator (A) in series with a filter (fig. 1). An air sampling rate of approximately 40 cubic feet per minute was selected, since at

Mr. Bradshaw, presently assigned to the Oak Ridge National Laboratory, Oak Ridge, Tenn., was formerly with the Robert A. Taft Sanitary Engineering Center of the Public Health Service, Cincinnati, Ohio. Dr. Setter is chemist in charge, radiological investigations, at the Center.

this flow the unit has an efficiency versus particle-size curve comparable to that of the upper respiratory system in man (1,2).

A nosepiece on the intake of the cyclone separator provided a face velocity of 25 liters per minute per square centimeter, which approximates the nasal air velocity of a man at work. Particles passing through the separator were caught on the glass fiber filter. These, constituting the secondary fraction, are the particles that might penetrate to the alveoli in actual breathing. They were deposited on an effective filter area of 63 square inches.

Procedure

The sampler was placed on the roof terrace off the east side of the auditorium of the Sanitary Engineering Center, approximately three stories above the ground. The sampling rate was adjusted by a bleeder valve on the high-volume blower (capacity of 60-80 cubic feet per minute) to 40.5 cubic feet per minute at the beginning of each sampling period. The sampling rate at 24 hours was rarely more than 10 percent below the initial rate. The average of the initial and final rates was taken for flow calculation.

Two samples were collected February 16-18, 1955, before the first United States test of nuclear weapons that month. From February

This is the Way We Brush—

Toothbrushes were given 70 students in the small, 4-room school in Espilola, near Babol, Iran, with instruction in oral hygiene. The school, completed last year with point 4 assistance and staffed by two young, enthusiastic teachers, is the first program demonstration of school health in the Caspian region.

The children have been weighed and measured and tested for hearing and vision. The doctor of the Babol Health Center gave them physical examinations. We hope to make arrangements with private physicians and the Ministry of Health Hospital in Babol to correct the children's serious physical defects. The sanitation division is setting up hand-washing facilities at the school.

Bandit Attack

Ethiopian bandits attacked one of our drilling supervisors, Robert House, between Jigjiga and Dik. Shot in the back and twice in the face, he miraculously escaped death. He was evacuated from Jigjiga to Addis Ababa, to Asmara, Eritrea, to Bahrein in the Persian Gulf, to Germany, and finally to the United States, where he is recovering.

—A. C. CURTIS, M.D., *chief, Health and Sanitation Division, U. S. Operations Mission, Ethiopia.*

Wan Phra Is Cleanup Day

Every "wan phra" is cleanup day in Panasnikom, Thailand. On the Buddhist weekly sabbath, the people clean their houses, the space underneath them, and their yards. The health committee roused interest in sanitation, and the resulting cleanup drive left the village spotless. Flowers and vegetables are planted in areas previously overgrown with weeds or cluttered with refuse.

Once Panasnikom's only source of drinking water during the dry season was a hole in the ground. The people walked down to the hole on rude planks and scooped up the muddy water at the bottom. Now they are building a water catch basin with shallow wells at two corners. International Cooperation Administration supplied pumps for the wells, which will be a year-round source of protected water.

The villagers themselves dug the wells and the catch basin, built the form for the well casings, and poured the casings and the slab. Sanitarians from Cholburi training center helped install the casings, slab, and pump.

Journey to Tobar Donoso

Anti-yaws campaign workers traveled for 8 days to reach the remote gold mining section of Tobar Donoso in northern Ecuador. Starting from the Colombian city of Tumace, they journeyed by railroad, boat, and pack animal into the Andes. All yaws cases and contacts in the isolated area were treated.

—JAMES D. CALDWELL, *chief, health, welfare and housing field party, U. S. Operations Mission, Ecuador.*

A Hut for the Zo

As a consequence of our classes in midwifery, the paramount chief in the small Liberian village we visited had built a hut where his wife, the head Zo, performs deliveries. In this and other villages the Gbarnga rural health unit holds classes for 135 midwives, or Zos. The classes concentrate on cleanliness, care of the umbilical cord, and recognition of abnormalities requiring medical attention.

In Sanniquellie we had a chance to compare our classes for midwives with the somewhat different system used by the hospital superintendent, a Liberian nurse who is English-trained. These Zos leave their families and villages and come to the Sanniquellie hospital for 1-1 or 15 months of experience. Except for housing, the midwives provide for all their own needs.

—JULIA WORTHINGTON, *adviser, Public Health Nursing, U. S. Operations Mission, Liberia.*

A calibration of the optical density developed on X-ray film from exposure to fission-product particles was made by using an isolated radioactive particle in the sample collected April 5, 1955. This particle of measured beta activity was used in a series of 8 exposures ranging from 5 minutes to 19 hours and in distance of particle to emulsion from 40 to 500 microns. The density (transmission) profile of a particle autoradiograph was determined with the aid of a microphotometer which viewed a film area 46 microns in diameter by means of magnification (1:10) and an aperture mask on the photocell.

Photometer readings were taken progressively from the center of the irradiated area outward until the density faded into background fog. From these readings the radiation exposures at the points of measurement were calculated (6) and used to equate the total radiation exposure received by the film. Since the radioactivity and length of exposure were known, a proportionality constant could then be calculated for each of the eight calibration exposures. The average of the eight proportionality constants was used to calculate the

radioactivity of air particulates from their autoradiographs. The calculated activity of a radioactive particle was then extrapolated from decay data to the activity at the midpoint of the collection time.

Autoradiographs of the more active particles, those which had an activity at mid-collection time greater than about 5 micromicrocuries ($\mu\mu\text{c.}$), were measured in this manner.

The minimum detectable activity by autoradiographic technique varies roughly as the square of the distance between the particle and the film emulsion. For a particle exposed for 24 hours and spaced 100 microns from the emulsion, the minimum detectable activity was estimated to be roughly 1 $\mu\mu\text{c.}$ All particles having an estimated radioactivity of less than 5 $\mu\mu\text{c.}$ were counted under a low-power microscope, and each was assumed to have an average activity of 2.3 $\mu\mu\text{c.}$

Gross Beta Activity

The gross beta radioactivity of particulate matter in each air sample is shown in figure

Figure 2. Gross beta activity of atmospheric particulates, Cincinnati, 1955.

Figure 1. Air sampler used in Cincinnati study of atmospheric radioactivity, 1955.

19 through April 9 and again from May 5 through May 12, sampling was continuous except for changing filters and emptying the cyclone separator. Samples were collected daily (20–28 hours) except for one 3-hour sample, four 2-day samples, and one 3-day sample (indicated by the width of the bar graphs in fig. 2).

After each collection the dust in the cyclone separator was removed with 100 ml. each of distilled wash and rinse water. Ten percent (20 ml. of the combined wash and rinse water) was filtered through a cellulose acetate membrane filter (*B*) for counting and autoradiographing the samples collected through March 22 and the sample collected on April 3. The filtrate, containing the soluble activity from the primary fraction, was evaporated to dryness in an aluminum dish (2 inches in diameter) and similarly counted in an internal counter. Twenty-milliliter aliquots of the primary fraction of all other samples were evaporated in dishes without filtration and counted, but no autoradiographs were made. Repeat counts of some samples were made to establish radioactive decay rates.

For assay of the secondary fraction, a $1\frac{1}{8}$ -

inch diameter circle ($\frac{1}{23}$ of the total filter area) was punched from the center of the glass fiber filter, counted in an internal proportional counter, and used for autoradiography.

The samples were held at least 4 and usually 16 or more hours after collection to permit decay of radon daughter activity ($T_{1/2}=38$ minutes) before the beta-gamma mixed fission product activity was counted in an internal gas-flow proportional counter having an efficiency of 50 percent (3–5). The measured activity of a sample was corrected for decay to the midpoint of the collection time from decay data or by the application of the exponential decay factor of -1.2 for fission-product activity formed on the most probable test date.

One to four days after collection, six membrane or glass-fiber filter samples were glued face up on a 5- x 7-inch sheet of paper. The sheet was then inverted on top of the emulsion of an X-ray film (*C*). A sponge rubber pad mounted on a 5- x 7-inch piece of plywood was placed on the inverted paper and weighted with a 16-lb. brick. The film was usually exposed for 20 to 25 hours before development for normal contrast with standard X-ray chemicals, according to the manufacturer's directions.

Figure 4. Radioactivity of particles as measured by autoradiographs, Cincinnati, 1955.

as many radioactive particles appeared on the 3-day autoradiographs as on the corresponding 24-hour film exposures. Thus, prolonged film exposure reveals a preponderance of particles with less than 1 $\mu\mu\text{c}$. of activity. It will be shown (fig. 4 and the table) that a large percentage of the total beta activity is not accounted for by the autoradiographic technique. It is likely that an appreciable part of the low-level activity from discrete particles merely increases the background fog of a 24-hour film exposure.

The particle with an estimated radioactivity of 1,700 $\mu\mu\text{c}$. was found in 10 percent of the primary fraction of the 24-hour sample collected at noon April 5. Subsequent autoradio-

graphs of the entire primary sample did not reveal any more particles of activity exceeding 500 $\mu\mu\text{c}$. The 1,700- $\mu\mu\text{c}$. particle was isolated from the mass of nonradioactive particles in the sample. It was a reddish, semitransparent, nearly spherical particle having a diameter of 7.5 microns. Its decay and absorption data were characteristic of 8-day-old mixed fission product.

Distribution and Frequency

On the basis of estimates obtained either photometrically or by microscopic examination, the particles were grouped into five ranges of beta activity. The percentage distribution of

2. (Gross beta activity is counted at an efficiency of 50 percent and includes gamma activity which is counted at an efficiency of 1 to 3 percent.) The lower level of beta activity found in 5 daily samples collected February 19 or later and the 2 collections made a few days before that date (not shown in the chart) ranged from 0.3 to 1 $\mu\text{c.}$ per cubic meter (1 $\mu\text{c.}/\text{m.}^3 = 10^{-12}$ $\mu\text{c.}/\text{ml.}$). The remaining 44 samples had an activity between 1 and 30 $\mu\text{c.}$ per cubic meter. Eight samples had an activity exceeding 10 $\mu\text{c.}$ per cubic meter. The average activity of all samples was approximately 5 $\mu\text{c.}$ per cubic meter.

The highest levels of activity observed in this study appeared 2 to 4 days following the reported detonation of nuclear devices in Nevada. Decay data of the air particulate samples and some rain samples were used to identify the radioactivity with specific nuclear weapons tests, as shown in figure 2.

The beta activity of particles in the primary fraction ranged from 0.08 to 17 $\mu\text{c.}$ per cubic meter, with an average of 1.7. The minimum value was found in the sample collected February 17. The activity of this sample had a half-life of several months. The maximum activity of a single particle was 1,700 $\mu\text{c.}$, found in the April 5 sample. This was the particle used for calibrating the autoradiographic technique.

Of the average activity of 5 $\mu\text{c.}$ per cubic meter in air particulates, an average of 1.7 $\mu\text{c.}$, or 34 percent of the total, was found in the primary fraction. Based on 28 samples available for comparison, from 1 to 41 percent, or an average of 16 percent, of the activity in the primary fraction was dissolved in the water used to remove the particles from the cyclone separator.

Autoradiographic Assay

Both the primary and secondary fractions of most of the samples collected from February 21 through March 19 and the sample collected on April 3 were autoradiographed after separating the water-soluble activity in the primary fraction. The autoradiographs revealed 106 active particles which were measured by photometry and 2,084 particles detected by microscopic examination.

The number of radioactive particles of variable beta activity represented an extremely small percentage of the total particles in the air, but, considering that a single person inhales 15 to 20 cubic meters of air daily, the particle radioactivity may have health significance. The variation in the number of radioactive particles in the 28 samples assayed by the autoradiographic technique is presented in figure 3. Excluding the samples of February 23 and March 1, for which only the primary fraction particles are given, the bar graph shows that all but 5 of 26 samples contained more than 1 radioactive particle per 10 cubic meters. In 5 samples there were from 16 to 82 radioactive particles per 10 cubic meters, as compared with a 26-sample average of 6.7 and a median of 4.

The beta activity of these particles ranged from an estimated minimum of 1 $\mu\text{c.}$ for detection by a 24-hour film exposure up to 1,700 $\mu\text{c.}$ for the most active particle. Three-day film exposures were also made on the samples collected February 21 and 22. About 3 times

Figure 3. Frequency of radioactive particles, Cincinnati, 1955.

man. The rest would penetrate into the alveoli of the lungs. Presumably 50 percent might lodge in lung tissue for a variable time. Most of the particles in this secondary fraction had an activity of less than 5 μc . per particle.

Some of the particles found in the primary fraction, however, might reach lung tissue. Some of these particles had much higher radioactivity than the secondary fraction particles. One particle with an activity of 1,700 μc . had a diameter of 7.5 microns. Its size was such that if the particle were inhaled it would have a finite chance of reaching the alveoli. Once there, the particle would probably remain to cause considerable radiation damage to local lung tissue. When inhaled the smaller particles are more likely to reach lung tissue, but they may be eliminated by several mechanisms (8-11).

Summary

Radioactive particles found in air samples collected in Cincinnati following nuclear detonations in Nevada were separated into two size-fractions representative of particles retained by the upper and the lower respiratory system of man. Air sampling was continuous from mid-February until early April and again for 1 week in May 1955.

Measurements by autoradiographs and gross internal proportional counting indicated that:

1. The maximum, minimum, and average concentrations of beta activity in 47 samples collected between February 16 and April 9 and 4 samples collected between May 5 and May 12 were 30, 0.35, and 5 μc . per cubic meter of air, respectively. For comparison, the maximum permissible level for unknown radioisotopes beyond the control area is 1,000 μc . per cubic meter of air.

2. The average number of radioactive particles per 10 cubic meters of air was 6.7 in 26 samples collected between February 21 and March 19 and on April 3. The weighted average beta activity of these samples was 37 μc . per 100 cubic meters of air. One sample contained as many as 80 radioactive particles and a beta activity of 300 μc . in 10 cubic meters of air.

3. The more radioactive particles were col-

lected by a cyclone separator, which simulates capture of particles by the nasal passages and bronchial tubes. Generally these particles would be rapidly eliminated from the human system. In roughly half of the samples tested, these particles had a gross beta activity of 25 to 500 μc . and one isolated particle of 7.5 micron diameter had an activity of 1,700 μc .

4. The activity of particles caught on the filter, representing material which would penetrate to the lung alveoli, was usually less than 5 μc . and did not exceed 25 μc . per particle.

activity in each fraction and in each radioactivity range as related to the total radioactivity of each daily sample is shown in figure 4. Particles containing 125-500 $\mu\text{mc.}$ were found only in the primary fraction of five samples. It is estimated that 10 to 37 percent of the total activity of these 5 individual samples resided in the "hot" particles. The samples collected March 8 and 9 each had particles with activities of 25 to 125 $\mu\text{mc.}$, which accounted for 20-25 percent of their radioactivity and were recovered from the primary fraction. A considerable portion of particles in the primary fraction also had a radioactivity of 1 to 25 $\mu\text{mc.}$

The activity of particles in the secondary fraction was usually less than 5 $\mu\text{mc.}$ per particle, but 6 samples had secondary-fraction particles having an activity of 5 to 25 $\mu\text{mc.}$ Figure 4 shows that at most only 61 percent of the total radioactivity of a sample was observed by the autoradiographic technique. This may be explained as follows: (a) the secondary fraction of three samples was not autoradiographed; (b) particles having an activity of less than about 1 $\mu\text{mc.}$ contributed only background fog to the X-ray films and this activity could not be measured; (c) the assumed average activity of

2.3 $\mu\text{mc.}$ for particles having an activity of 1-5 $\mu\text{mc.}$ each may be an underestimate; and (d) the autoradiographic technique is at best a rough estimate of particle radioactivity.

The results are further summarized in the table to show the frequency of occurrence of radioactive particles in the atmosphere tested. The most radioactive particle found (1,700 $\mu\text{mc.}$) had a diameter of only 7.5 microns. It appeared in the primary fraction and theoretically would occur at a frequency of 6 particles per 1,000 cubic meters of air, whereas a maximum of 13 and an average of 1.5 particles having an activity of 125-500 $\mu\text{mc.}$ would occur per 1,000 cubic meters of air. The great preponderance of radioactive particles were found to have low activity levels of 1-5 $\mu\text{mc.}$; they were much more abundant in the secondary fraction. There were no particles in the secondary fraction which had an activity exceeding 25 $\mu\text{mc.}$

Of the radioactivity in each fraction an average of 57 percent was accounted for by autoradiography in the primary fraction, and an average of 23 percent was accounted for by autoradiography in the secondary fraction. Considering the radioactivity of both fractions, a maximum of 61, a minimum of 9, and an average of 36 percent of the total radioactivity was accountable by the autoradiographic technique.

Occurrence of particles of given radioactivity, Cincinnati, 1955

Particle activity range, $\mu\text{mc.}$	Primary fraction		Secondary fraction	
	Maximum	Average	Maximum	Average

1-5-----	8 35	1 17	73 5	5 2
5-25...	38	12	1 5	16
25-125	13	025	0	-
125-500	13	015	0	-
1,700 --	1 06	-----	0	--
Percentage of fraction radioactivity in discrete particles ²				
1-500 -	89	57	51	23

¹ One particle in 10 percent of sample had a diameter of 7.5 microns and an activity of 1,700 $\mu\text{mc.}$

² Based on autoradiographic technique employing 24-hour film exposure and, in the case of the primary fraction, its soluble activity which varied from 1 to 41 or an average of 16 percent of the total primary activity.

Discussion

The maximum concentration of gross beta activity of 30 $\mu\text{mc.}$ per cubic meter of air in the samples collected in this study was far below the 1,000 $\mu\text{mc.}$ per cubic meter of air listed by the National Committee on Radiation Protection and Measurement as the provisional level for "permissible concentration of unknown mixtures of radioisotopes in the air . . . beyond the areas that are under the control of the installation responsible for the contamination." This value set by the committee is believed "to be safe for exposure to any of the radioisotopes for periods of a few months" (7).

About one-third of the total radioactivity of the air particulates collected in Cincinnati, that found in the primary fraction, would probably be retained in the upper respiratory system of

Diphtheria in the United States in 1956

HELEN A. MOORE, M.D.

DURING the autumn of 1955 and the early winter of 1955-56, diphtheria occurred in the Nation with a frequency not witnessed for a number of years. Fear of a definite resurgence was aroused when outbreaks occurred in areas which had been almost entirely free of the disease for extended periods. The particularly high incidence of the disease in the southeastern States has been described in a previous report (1) prepared at the close of 1955. It is the purpose of this paper briefly to summarize the United States diphtheria experience in 1956.

Data on the occurrence of diphtheria cases and deaths were obtained primarily from publications of the Public Health Service's National Office of Vital Statistics, *Morbidity and Mortality Weekly Reports* and their annual supplements and *Vital Statistics of the United States*. More detailed information was obtained from current communicable disease reports prepared by States for internal use and from the annual communicable disease statistics published by most States. Additional details were collected by personnel of the Communicable Disease Center in connection with field assignments which dealt directly or indirectly with diphtheria. The assembling and review of such data are continuing functions of the Surveillance Section of the Center.

The occurrence of diphtheria in 1955 and 1956, by weeks, is given in figure 1, and the States contributing heavily to the weekly peaks are also indicated. During the first half of 1956 diphtheria incidence continued to be relatively high and was above that of the preceding

year in about two-thirds of all weeks. Following the seasonal low, however, the expected pattern of early increase of diphtheria cases in the southern States did not develop to the usual extent. Incidence remained well below that of 1955 throughout the fall and winter, and at the close of the year 1,581 cases had been tentatively reported, compared with 2,039 cases in 1955. Data for 1956 in figures 2 and 3 and table 1 are also preliminary. Although final figures for 1956 are now available, they do not alter the pattern or change the conclusions since they change the total by less than 1 percent.

This 22 percent decrease in the incidence of diphtheria restores somewhat the trend of the last decade. After the last increase in reported diphtheria in 1945 there was a fairly steady decline at about 25 percent per year until 1953. In this year the decrease was only 20 percent. In 1954 it was 13 percent and in 1955 only 3 percent. The small drop in cases for the calendar year does not give as clear a picture as the statistics for the disease years. For the disease season of 1955-56, there was actually a 12 percent increase over the disease year 1954-55. The decline in cases in the calendar year of 1956 was due almost entirely to decreases in the last half of the year and in the southeastern States.

In figure 2 and table 1, diphtheria morbidity rates are shown by standard geographic divisions and by States for 1949-56. The areas showing the greatest decline in 1956 were the South Atlantic and East South Central States. Small decreases, or essentially no change, occurred in all other divisions except the East North Central and the Mountain States, which showed increases of 0.6 cases per 100,000 population.

The increased rate in the East North Central division is almost entirely due to increases in

Regional Medical Directors Reassigned

The Public Health Service has announced a series of changes among medical directors assigned to the regional offices of the Department of Health, Education, and Welfare. The changes will become effective July 1, 1958.

Dr. Francis J. Weber, medical director of Region 8, with headquarters in Denver, Colo., has been appointed chief of the Service's newly created Division of Radiological Health in Washington, D. C.

Dr. Michael Pescor, present medical director of Region 7, with headquarters in Dallas, Tex., will become medical director of the Denver office.

Dr. Richard Boyd, now medical director of Regions 1 and 2, stationed in New York City, will assume the same position in the Dallas office.

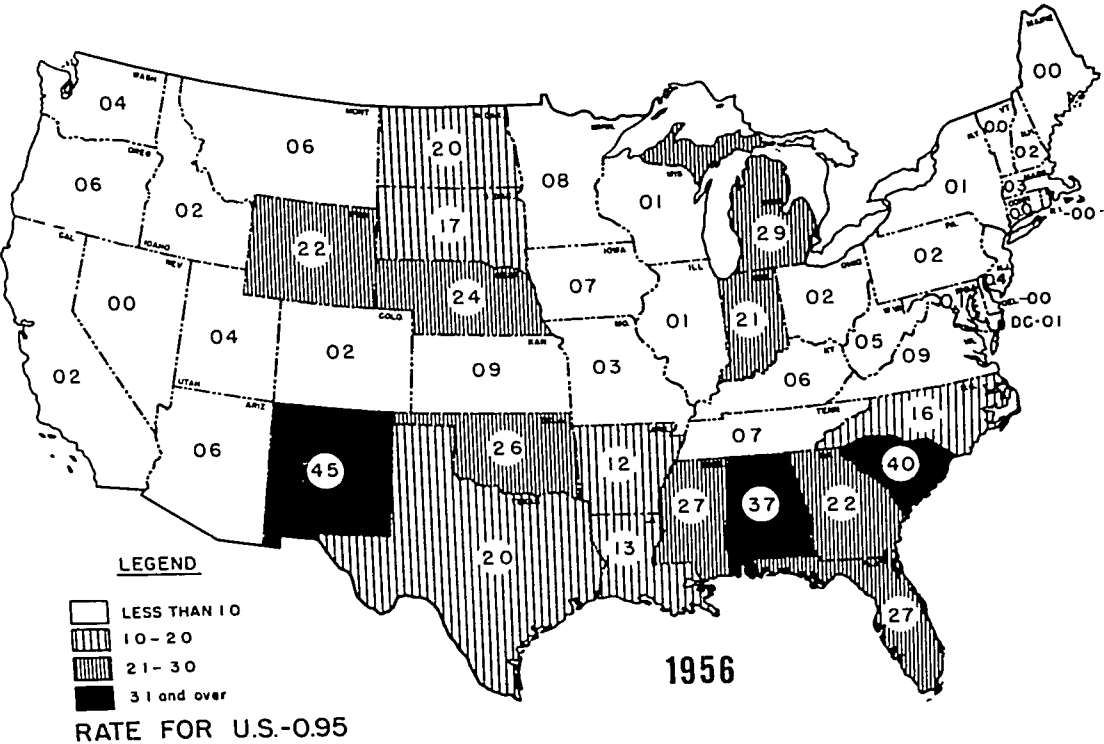

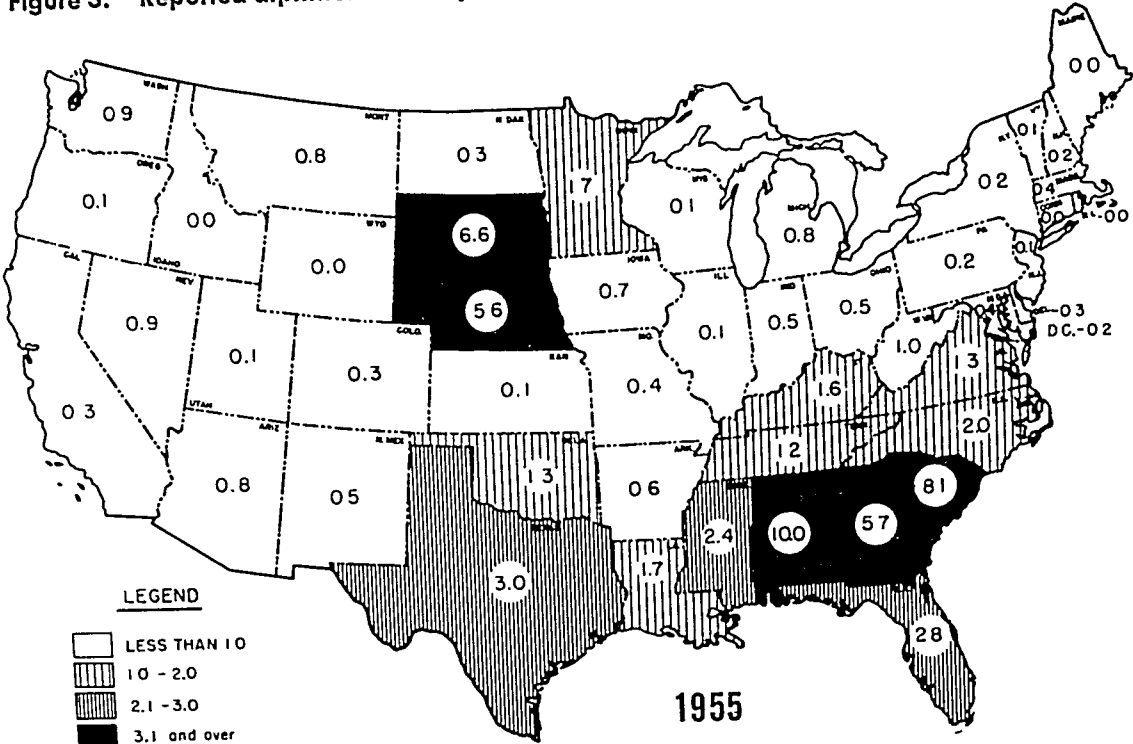

Dr. Harald M. Graning, medical director of Region 5, in Chicago, will move into the New York City position.

Dr. Arthur B. Price, at present on loan from the Public Health Service to the Bureau of Old-Age and Survivors Insurance, Social Security Administration in Baltimore, will become the medical director of the Chicago office.

The medical directors of other regions are: Dr. Eugene Gillis, Region 3, Charlottesville, Va.; Dr. Will H. Aufranc, Region 4, Atlanta, Ga.; Dr. Lewis H. Hoyle, Region 5, Kansas City, Mo.; and Dr. Charles F. Blankenship, Region 9, San Francisco.

The medical directors in the regional offices direct Public Health Service programs of grants and technical assistance and other relationships with the States and Territories that comprise each region.

Figure 3. Reported diphtheria cases per 100,000 population, United States, 1955 and 1956.

the States of Michigan and Indiana (fig. 3 and table 1). The rise in the Mountain States is attributable to an increase of 4 cases per 100,000 population in the reported incidence of diphtheria in New Mexico.

The prominence of the southern States in the persistent reporting of diphtheria is not greatly changed. In 1955, 74 percent of the Nation's cases were reported from the three southern divisions. In 1956, only 57 percent of the total occurred in this area but, again, this change only restores a previous relationship which was exaggerated in 1955.

Brief descriptions of diphtheria experience from localities (counties) reporting 10 or more diphtheria cases in 1956 are found in table 2. A county rate of 20 per 100,000 is used as a demarcation so that such local rates occurring in 1956 may be compared with those of 1955, as previously reported (1). In 1955, 19 localities had rates of 20 per 100,000 or higher. In 1956, only 9 localities reported cases at this or a higher rate.

A distinct localization of these sharp disease

episodes to the area east of the Mississippi River and south of the Ohio River was noted in 1955. Fourteen of the 19 outbreaks occurred in this area. In 1956, only three episodes occurred in

verely congested and housing is generally substandard.

Of the 141 cases occurring during the outbreak period, 126, or 89 percent, were mild.

Only 15 persons were moderately or severely ill. There were four deaths. Cultures positive for *Corynebacterium diphtheriae* were obtained from 101 of the 141 patients and from many

the same area. In table 2 it can be seen that one of these (Charleston County, S. C.) was a continuation of an outbreak which began in 1955, and the current rate in Charleston County, while high, is a considerable decrease from 1955. One (Pickens County, Ga.) is of doubtful authenticity and one (Calhoun County, Ala.) appears to be an actual sporadic outbreak beginning in 1956.

The occurrence of 64 cases of diphtheria in and about Michigan City, Ind., was a particularly sharp deviation from the recent experience of the area. The same was true of the incidence in Chaves County and Bernalillo County (Albuquerque), N. Mex.

Other areas in which the incidence of 1956 was unexpectedly high were Mercer County

(Trenton), N. J., Wyandotte County (Kansas City), Kans., Hillsborough County (Tampa), Fla., and Nueces County, Tex., but probably the most marked departure from recent trends occurred in the State of Michigan. Two counties, Kalamazoo and St. Clair, experienced noteworthy increases in cases and in Wayne County (Detroit) an outbreak of considerable size took place.

Within the city of Detroit 141 cases of diphtheria occurred during October, November, and December 1956, and a total of 167 cases were reported during the year. This was a ninefold increase over the median expectancy of the last 7 years. One hundred of the cases originated in an area of six census tracts in the southwestern section of the city. The area is se-

¹ Preliminary reports.

² U. S. Bureau of the Census: Population estimates. Series P-25, Nos. 145 and 148. Washington, D. C., U. S. Government Printing Office, 1956.

Source: Morbidity and Mortality Weekly Reports (National Office of Vital Statistics), January 4, 1957; Annual Supplement, September 27, 1957.

These stinging insects, nuisances as well as agricultural pests, can be controlled through intensive and extensive measures.

The Imported Fire Ant

F. G. FAVORITE, M.P.H.

THE IMPORTED fire ant (*Solenopsis saevissima richteri* Forel) (1), of concern to agriculture in the southeastern United States, is also a public health nuisance. Its sting is almost as painful as a honeybee's and can cause an anaphylactoid reaction.

These stinging ants, now reported in North Carolina, South Carolina, Georgia, Florida, Alabama, Mississippi, Arkansas, Tennessee, Louisiana, and Texas, were first introduced into the United States at Mobile, Ala., around 1920 (fig. 1). Presumably the ants gained entry into the country as stowaways on vessels arriving from South America, the normal habitat of this species (2).

The imported fire ant cannot and is not being ignored. To control it, the Federal Government has designated \$2,400,000 in matching funds for States that suffer from infestations. Alabama has allocated \$155,000; Georgia, \$250,000; and bills for funds have been presented in other State legislatures. Both intensive and extensive measures will be required to halt this insect short of its geographic reproduction limit.

The imported fire ant is not unlike many other ants in general appearance, but it differs considerably in habits and microstructure. The fire ants are classed as medium sized. The worker minors, females of immature colonies, average approximately $\frac{1}{8}$ inch in length, whereas the worker majors, females, usually sterile, of mature colonies, average $\frac{1}{4}$ inch.

Captain Favorite, MSC, U. S. Army, is chief of the Entomology Section, 3d Army Medical Laboratory, Fort McPherson, Ga.

The basic color varies by geographic location from rust red to dark brown.

Identification of the imported fire ant is dependent upon careful examination to separate it from closely related species of the genus *Solenopsis*. The major form of *S. geminata*, the tropical fire ant, has an extremely large head out of proportion to the rest of the body and mandibles usually without teeth. Its antennal scape (the first segment of the antenna) reaches only one-half to two-thirds the distance to the posterior margin of the head. In the major form of *S. alyoni*, the southern fire ant, the mandible usually has three teeth and its antennal scape does not extend beyond two-thirds the distance to the posterior margin of the head.

The major form of *S. saevissima richteri*, the imported fire ant, normally has four mandibular teeth, and its antennal scape extends two-thirds or more the distance to the posterior margin of the head (fig. 2).

Biology

The imported fire ant's nest, or mound, also identifies it, for these ants do not build an elevated mound with the central entrance common to many other species. Fire ant mounds vary in construction to suit the environment. When the colony is free to develop without interference, the mound grows to a height of 18 to 24 inches with a basal diameter of approximately 24 inches. The active mound becomes hard in texture after alternate wetting and baking from exposure. The hardened mounds have caused damage to farming equipment (3, 4).

When colonies develop in lawns where they

carriers. Two types of organisms were found and the two strains were greatly different in toxogenicity (virulence).

There had not been what could be construed as serious neglect of immunization in the area of the outbreak, although the immunization levels were not as high as in some other areas of the city. Some contiguous census tracts with the same, or lower, immunization rates were not affected by the outbreak. Again, it was demonstrated that diphtheria can occur in outbreak proportions in places where the immunization levels are at or above those currently thought to be "adequate."

Summary

1. An increase in reported diphtheria during the disease year of 1955-56 is noted. During the first half of the disease year of 1956-57, including the seasonal peak, weekly incidence was well below that in the preceding year.

2. Diphtheria morbidity rates for 1956 fell most noticeably in the South Atlantic and East South Central States. Increases were noted in the East North Central and the Mountain States.

3. Localized diphtheria outbreaks decreased

in the Southeast and increased in other areas but the total of such episodes in the Nation was lower than in 1955.

The relative absence of localized sharp outbreaks of diphtheria in rural regions of the southeastern States must account for a portion of the decrease in this area. A sparing effect from the preceding high season might be postulated; however, it has been noted that such outbreaks seldom affect the same locality or even adjacent localities in successive years. Decreases were noted also in some of the southern population centers which have been persistent foci. If this be accounted an expected cyclic variation, it is not one which has been very obvious in recent years (fig. 2).

4. The recurrence of outbreaks in northern urban centers might be taken as a fairly ominous sign; one calling for an "agonizing reappraisal" of present definitions of "adequate" immunization levels.

Institutes on Nuclear Energy

Nine institutes on nuclear energy for engineering educators will be held in the summer of 1958 at universities and laboratories throughout the Nation. Sponsored by the Atomic Energy Commission and the American Society for Engineering Education, the institutes will provide special training in nuclear energy and the nature of nuclear reactor problems which the educators can incorporate into their teaching.

There will be 4 basic courses for those with no background in nuclear energy, 4 advanced courses, and a basic course for teachers in technical institutes. Applications for the institutes can be obtained from deans of engineering or the society's headquarters. Address W. Leighton Collins, Secretary, American Society for Engineering Education, University of Illinois, Urbana, Ill.

bles to make an incision to receive the stinger (5). My observation of stings received while preparing this study differs from these reports; discrete stings were received while the mandibular anchor was retained.

Insertion of the stinger brings immediate pain almost comparable to the sting of a honeybee. Within several minutes a wheal, 4 to 8 mm. in diameter, appears. The stinging sensation usually subsides by the time the wheal appears. Within 24 hours a pustule, 2 to 3 mm. in diameter, forms in the center of the wheal. The pustule persists for 3 to 8 days until the purulent material is absorbed or sloughed. Each sting leaves a smooth pink area 2 to 4 mm. in diameter for several weeks until the gradual formation of scar tissue takes place (fig. 3).

During 1957 at Fort Benning, Ga., where most of my observations were made, approximately 300 persons, mainly dependents of military personnel, reported for medical care of imported fire ant stings. The majority of these persons received their stings on the lower leg and forearm while they were working or playing near their residences.

Five persons, 2 adults and 3 children, manifested anaphylactoid-type reactions. One girl reacted severely to a fifth sting, although she demonstrated no sensitivity to any of four previous stings. Following the fifth sting she suffered total body edema, cyanosis around the mouth, and respiratory embarrassment. An adult male fainted 3 times shortly after receiving 4 stings about the ankles. On examination hives were observed.

Treatment of children by parenteral route with 1:1,000 epinephrine graduated in dosage from 0.1 cc. in infants to 1.0 cc. when the child's weight exceeds 100 pounds, and of adults with 1.5 cc. of injectable benadryl solution (15 mg.) by deep intramuscular route, plus oral administration of antihistamines in both groups, has been successful in controlling most reactions to fire ant stings.

While this study was being prepared, a second instance of imported fire ant infestation of a military installation occurred at Fort McPherson, Ga., approximately 100 miles from Fort Benning. The ants were observed by a medical officer who had attended an orientation on the problem some 10 days earlier. Because

Figure 3. Fire ant stings at 72 hours.

it had been quickly identified, the colony was treated while it was still immature, the majority of the ants being worker minors; it is believed that the infestation was eradicated before it had the opportunity to spread.

Even so, in the 24 hours between discovery and treatment the colony had moved approximately 4 feet from the original site. Considerable motor vehicle travel between the two military posts clearly provided a means of transportation for the imported fire ant. Local increases also occur during the spring mating season when the winged queen, having mated in flight, starts a new colony wherever she alights.

Control

Granular formulations of hydrocarbon insecticides seem to offer more promise for control than any other method. Both dieldrin and heptachlor at 5 percent concentration, spread

Figure 1. Spread of the imported fire ant in the southeastern United States, 1918-57.

U. S. Department of Agriculture

are frequently disturbed by grass-cutting equipment, the ants modify the architecture of the mound to a spreading nest, irregular in shape, covering 3 to 5 square feet, and rarely more than an inch or two high. On slopes where grass cutting is infrequent, the colonies usually select a hillock or a raised clump of weeds for the mound. When it is repeatedly disturbed or when its food supply becomes scarce, the colony moves to a new location, usually within 25 feet of the original site. Or the colony divides into 2 or 3 smaller ones, and the ants rebuild each colony to maximum strength.

Mature fire ant colonies house as many as

25,000 insects. In the colonies I observed, the greatest proportion of the ants were worker majors equipped with a pugnacious temperament and competent stinging apparatus. Several queens may be in the same colony.

In feeding habits the ants are practically omnivorous. Primary food is obtained from the seedlings, roots, and subsurface portions of plants and grasses (3-5). There are also records of ants attacking clutches of eggs, entering the pipped eggs, and feeding on the young within (4, 5).

Effect on Persons

When the fire ant mound is disturbed, the insects bubble forth in the thousands and within seconds the colony can administer 3,000 to 5,000 stings on an invader. The ants move rapidly, stinging almost immediately on contact with the skin, and are prone to sting 3 or 4 times.

Normally, the ant seizes with its mandibles an anchor on a hair or the skin, quickly moves the abdomen under itself, and drives the stinger into the skin. The stinger remains implanted for 3 to 7 seconds before it is withdrawn, and the ant either pivots on its mandibular anchor or moves a short distance to repeat the stinging process. Second and third stings are usually of less duration but still quite painful.

Reports have said that the ant uses its mandi-

Figure 2. Distinguishing characteristics of three species of *Solenopsis*: *S. geminata* the tropical fire ant, *S. xyloni* the southern fire ant, and *S. richteri* the imported fire ant (m=mandible, s=scape).

Mandatory Federal inspection of poultry will not eliminate all unfit poultry from the consumer market. States and municipalities have the major responsibility for regulating the poultry industry's intrastate production and distribution.

Federal and State Poultry Programs

JOE W. ATKINSON, D.V.M.

ALL GROUPS concerned agree on the need for official poultry hygiene inspection. This was demonstrated during hearings in 1956 and 1957 before five congressional committees (1-5). What makes such inspection necessary? What should its objectives be? How can those objectives be attained? Where do basic responsibilities rest, and what is the present picture in relation to those responsibilities?

The problems necessitating official poultry hygiene inspection and supervision fall under three general headings: diseased poultry, insanitary plants and products, and conditions not apparent to the consumer.

Diseased Poultry

Other workers (6-10) have dealt extensively with poultry diseases as public health problems. Therefore, it is sufficient to point out that infected birds may transmit a disease, such as psittacosis, to poultry plant employees or other persons who dress or eviscerate them, or they may serve as a source of a foodborne disease, such as salmonellosis. Consumers do not want to buy food derived from or contaminated by

Dr. Atkinson is consultant, Poultry Inspection and Sanitation, Milk and Food Program, Division of Sanitary Engineering Services, Public Health Service. This paper is based on an address at the Sixth Annual Health Conference, University Park, Pa., August 20, 1957.

diseased birds, nor do plant employees wish to handle badly diseased poultry, even when there is no health hazard.

Diseased poultry originates, of course, at the farm or producer level. Reports in 1956 by the Committee on Poultry Diseases, American Veterinary Medical Association (11), and the Committee on Transmissible Diseases of Poultry, U. S. Livestock Sanitary Association (12), indicate the continuing nature of this problem. The latter report states:

"In reviewing the research work in the field of poultry diseases that has been done during the past year, one is aware that progress is being made, however slowly, in the knowledge and control of transmissible diseases of poultry. New problems, such as synovitis and ornithosis, increased in importance while others, such as hemorrhagic syndrome of chickens, decreased in incidence during the past year. In general, however, the major problems, such as leukosis, respiratory diseases, salmonellosis, and others, that have confronted us in the past are still the major problems of today."

Unfortunately, diseased poultry does not remain at the farm or producer level. Some of it goes to be processed and, unless rejected at that point, enters retail food channels.

While the vast majority of poultry sold for processing is healthy, a substantial amount is diseased. For example, the U. S. Department of Agriculture, under its voluntary poultry inspection program, inspected about 30 percent

at the rate of 40 pounds per acre, obtaining 2 pounds of technical material per acre, were successfully used during the summer of 1957. Chlordane has been used at the rate of 4 pounds of technical material per acre (6-8). Seeding machinery or another type of equipment which affords an even coverage can be utilized for spreading. I feel that watering the ground following treatment is essential to gain dispersion of the chemical and reduce the toxic hazard to human beings and domestic animals.

In addition, mounds should be treated individually by excavation, direct insecticide application, and watering. However, mound treatment alone cannot be relied upon for eradication. Following such treatment the ants move from the immediate area and the survivors establish a new colony.

Previously treated areas indicate that the method of spreading and treating mounds individually with insecticides will prove effective for at least 2 years (7), when preventing reinfestation may be necessary. The cost of the control program will vary with the insecticide selected, method of application, and the cost of labor in the community, but experience indicates that an average figure in the southeast would be approximately \$5 per acre.

The use of a toxic chemical introduces an-

other public health hazard, but if the chemical is applied by qualified personnel under proper supervision, the hazard can be nullified.

Environmental Engineering Curriculum

Rensselaer Polytechnic Institute in Troy, N. Y., will offer full programs in the newly developed field of environmental engineering beginning in the fall of 1958.

At that time, a 4-year undergraduate curriculum leading to the degree of bachelor of environmental engineering and graduate courses leading to advanced degrees will be put into effect.

The object is to train engineers to meet environmental problems created by a growing population, industrial expansion, and increased urbanization.

Water conservation, food supply, air pollution control, and problems associated with the nuclear industry will be studied. Other courses will deal with industrial safety, waste treatment and disposal, housing, insect and rodent control, and research.

The new curriculum was developed in consultation with engineers and health officials at all levels of government.

eviscerating the bird or observing its evisceration, she rejected any carcass with abscesses, tumors, obnoxious exudates, badly swollen or discolored liver, or other abnormal or questionable conditions. She could also be sure that the edible carcass and giblets were not soiled with filth during evisceration.

Today, most housewives select their poultry and poultry products, either ready-to-cook or precooked, from a large variety displayed in the retail market. In addition, many servings of poultry and poultry dishes are consumed in public eating establishments. The consumer does not see the live bird or observe its processing.

So far as consumer knowledge or surveillance is concerned, abscesses, tumors, and diseased organs or parts could be removed from unfit poultry carcasses and the remainder sold as ready-to-cook poultry. Birds which are diseased, emaciated, or so altered in appearance as to be unsalable as ready-to-cook poultry can be processed, sold, and served as one of the numerous poultry dishes that preclude even an expert's evaluation of its original condition.

Similarly, insanitation may be completely hidden from the consumer. Poultry soiled by feces or other wastes can be washed off or processed so that the ultimate consumer will never be aware of the soiling, even though a seedbed of bacteria may remain (15). A good example of this is New York dressed poultry. Often grossly contaminated during chilling or other handling pending delayed evisceration, a very small proportion of such poultry actually reaches the ultimate purchaser in the uneviscerated form. Much of it is finally eviscerated in processing plants or retail markets and sold to the consumer as "fresh" ready-to-cook poultry. Most of the remainder is eventually used in various precooked poultry products or served in public eating establishments to the unaware consumer.

Other less serious but nevertheless objectionable practices may be inapparent to the purchaser. For example, frozen poultry may be defrosted and sold as "fresh." Unfrozen poultry may be held too long in distribution channels and sold to the housewife as "fresh" poultry, when in fact its freshness is substantially deteriorated and its storage life prac-

tically exhausted. Such practices have even involved products treated with antibiotics to extend storage life.

Objectives of Poultry Hygiene

In view of these problems, what should be the basic objectives of official poultry hygiene programs? Health and consumer groups agree that they certainly should provide:

- Protection of the consumer's health and interests by preventing the processing, distribution, sale, and consumption of diseased, insanitary, or otherwise adulterated poultry or poultry products.

- Assurance that poultry and poultry products have not been altered or treated to conceal inferiority, that they are factually and informatively labeled, and that they are prepared, packaged, and distributed so as to protect against contamination and spoilage to the point of purchase by the ultimate consumer.

- Protection of the health of poultry industry personnel to the fullest extent practicable.

Among the specific steps that can be taken to attain these objectives are:

1. Antemortem inspection of all poultry to be slaughtered, and elimination of birds determined to be unfit for food.

2. Postmortem inspection of each carcass and its viscera at the time of evisceration, immediately following slaughtering and defeathering.

3. Inspection of the processing of poultry pies, patties, soups, dinners, and stuffed or breaded poultry.

4. Reinspection of poultry and poultry products whenever necessary to assure continued fitness for use as food.

5. Destruction or denaturing of condemned live birds and other condemned poultry and products.

6. Supervision of sanitation in processing plants and during storage and distribution.

7. Supervision of the labeling and identification of the product.

8. Cooperation between inspection agencies and livestock disease control officials to control and prevent diseases in poultry.

9. Investigation and corrective or preventive measures when foodborne disease outbreaks are attributed to poultry, and when disease out-

of the poultry sold off farms in 1936, or more than 1.4 billion pounds. The amount rejected 11,270,951 pounds, was a little less than 0.8 percent of the total inspected. But this is a sizable amount considering the number of individual servings of poultry meat or products that could have been obtained from 11 million pounds of poultry.

What happens to diseased poultry which is processed under makeshift conditions on the farm, in retail markets, restaurants, or hotel kitchens, or in plants lacking official inspection? Obviously, the consumer has no assurance that unfit birds will be rejected in the absence of official inspection for wholesomeness. Even if financial or other personal considerations were not of primary concern to them, the persons involved seldom have the training or experience necessary to evaluate diseased poultry objectively from the health and consumer viewpoints.

A similar, related problem exists with poultry processed in the absence of continuous official supervision for sanitation.

Insanitary Plants and Products

There is some reason to believe that insanitary conditions, as well as diseased poultry, may contribute to the relatively high incidence of illness among employees in the poultry processing industry. Speaking at the Institute of American Poultry Industries Annual Fact Finding Conference in 1955, Victor Pringle, president, Associated Poultry and Egg Industries, stated: "One firm I know saved \$12,000 last year in compensation insurance, by controlling infections and skin rashes, thanks mainly to a better sanitation program throughout all parts of its plants."

It must be emphasized that far too little is known about the specific illnesses which affect poultry plant workers and the exact causative factors. According to Bureau of Labor Statistics reports, the injury frequency rate in the poultry and small game dressing and packing industry is almost three times the average of 135 manufacturing industries (13). The scope and significance of workers' health problems call for careful study and evaluation and the application of all practicable safeguards.

With respect to foodborne disease outbreaks, also, our information is incomplete. Insanitary conditions or the lack of adequate refrigeration during processing and distributing or during preparation and serving undoubtedly cause many of the outbreaks. Here, again, the application of known sanitary safeguards should be accompanied by continuing research and epidemiological studies to delineate the problem more definitely. Of course, any of a number of conditions or operations in poultry processing establishments may cause insanitary products (14). These conditions are particularly significant.

- Diseased poultry slaughtered for processing may contaminate facilities, equipment, employees' hands, and otherwise clean, healthy poultry.

- Mass contamination may occur when un-eviscerated (New York dressed) carcasses are held for delayed evisceration (15-18), particularly when chilled in water or ice slush, packed or shipped in cracked ice, or frozen and subsequently defrosted for evisceration.

- Building facilities or equipment may be inadequate for the volume or type of processing operations, making sanitation a practical impossibility. When poultry is dressed or eviscerated in retail markets, restaurants, or hotel kitchens, conditions are also conducive to contamination of other foods with feces and other wastes from the birds.

- Processing, particularly evisceration of carcasses, may be conducted at such high speeds that carcasses are frequently contaminated with feces or other filth.

These conditions, as well as others, may exist completely unknown to the ultimate consumer.

Conditions Inapparent to Consumer

Because of present marketing practices and buying habits, the average consumer has little personal knowledge concerning poultry and poultry products. This was not true years ago.

Formerly, the average family ate most of its meals in the home. The housewife selected her poultry live at the farm or market. Although not qualified to make a professional evaluation, she quickly refused any bird which did not appear to be bright and healthy. Similarly, upon

(except for overtime and holiday work) to be paid through appropriations to the Department of Agriculture.

2. Application of the act to the extent deemed desirable by the Secretary of Agriculture in certain areas of intrastate commerce, to be designated by him after hearings called at the request of certain State or local official agencies or industry groups.

3. Antemortem inspection of poultry to the extent deemed necessary by the Secretary of Agriculture.

4. Postmortem inspection of the carcass of each bird processed.

5. Condemnation of unwholesome or adulterated carcasses, parts, and products, and supervision over disposition of condemned material.

6. Approved labeling, including application of inspection legend, of all containers of product passed as wholesome and unadulterated.

7. Official supervision of all sanitation facilities and practices in plants under Department of Agriculture inspection; inspection to be withheld from plants not complying with such regulations as may be promulgated by the Secretary of Agriculture.

8. Movement of uneviscerated poultry carcasses (New York dressed poultry) outside the plant where slaughtered only as authorized by and under rules and regulations prescribed by the Secretary of Agriculture.

9. Prohibition of various actions which would circumvent the intent of the law; injunction proceedings and penalties for violations.

10. Maintenance of records for 2 years on the receipt, delivery, sale, movement, or disposition of poultry or poultry products in interstate or foreign commerce or in a designated area.

11. Exemptions for (a) producers who sell poultry directly to household consumers or restaurants, hotels, and boarding houses for use in their own dining rooms or in the preparation of meals for sale direct to consumers only, provided that such producers buy or sell no poultry products other than those produced from poultry raised on their own farms; (b) retail dealers who cut up ready-to-cook poultry for sale directly on the premises to retail consum-

ers; (c) other persons as deemed practicable until but not after July 1, 1960; and (d) persons processing poultry as required by recognized religious dietary laws, to the extent determined necessary by the Secretary of Agriculture to avoid conflict with such requirements while still effectuating the purposes of the act.

12. Regulation of imported slaughtered poultry or parts or products thereof.

13. Exemption of poultry and poultry products, insofar as regulated by the act, from the provisions of the Federal Food, Drug, and Cosmetic Act.

14. Cooperation by the Secretary of Agriculture with other branches of government and with State agencies in carrying out the provisions of the act.

15. Application of the act after January 1, 1958, to persons applying for Department of Agriculture inspection under the act and meeting all requirements; mandatory application of the act beginning January 1, 1959.

Problems Remain for States

After the new Federal law goes into effect, however, State and local agencies will still have major responsibilities for effective poultry hygiene programs.

1. The Department of Agriculture service will be provided only in processing plants; foodborne disease is often caused by mishandling of products during local distribution and in retail establishments.

2. Approximately 1,000 interstate processing plants will have Department of Agriculture service by 1960 under the new law, but there are about 2,500 intrastate plants. Some of the latter may be designated to come under the Federal law a few years from now, but the majority will remain a responsibility for State and local agencies and could become a dumping ground for diseased flocks, unless effective State and local programs are developed and maintained.

3. Certain exemptions are permitted under the Federal act which could result in the delivery of significant quantities of uninspected poultry directly to hotels, restaurants, and boarding houses. State and local ordinances

breaks occur among the employees of poultry processing plants.

10. Continuing research and field studies to delineate more definitely the health hazards associated with processing and consuming poultry and to develop increasingly effective safeguards.

Where Responsibility Rests

The concept of "let the buyer beware" cannot be applicable to foods. Recognizing his inability as an individual to make sure of the safety and acceptability of foods, the consumer looks to government for assurance and protection. While the food processor has a basic responsibility for his product, governmental agencies have found it necessary to provide various regulatory programs to guide and assist the food industries, and to protect against both unintentional and premeditated actions which may be detrimental to the health and welfare of the public.

In this country, State and local governments have primary responsibility for protecting the health and welfare of the citizens within their jurisdictions. Logically, this responsibility is usually assigned or delegated to the State and local health agencies. In turn, these agencies may seek, from Federal or other sources, specific assistance or guidance when research, field studies, or developmental work beyond the resources of one State or municipality is needed. The Public Health Service receives numerous requests of this nature.

On the other hand, a problem may be partly interstate in scope and can best be approached at the interstate level by the Federal Government. In either case, basic public health responsibility generally remains with the State and local health agencies. Because of the mass production and widespread distribution of many foods, this has been the pattern in food hygiene.

Thus, the Public Health Service provides technical assistance, develops program guides and training aids, conducts training courses, and engages in and supports research and investigations to aid States and municipalities in their milk and food programs. Upon the recommendation of both the Association of

State and Territorial Health Officers and the U. S. Livestock Sanitary Association, the Service developed a model ordinance covering sanitation in poultry processing and marketing (19-21).

The Food and Drug Administration inspects poultry processing plants engaged in interstate commerce and examines products shipped interstate. For almost 30 years the Department of Agriculture has provided voluntary inspection and sanitation services (22, 23) to poultry processors who apply and pay fees for it and who comply with regulations. This service seldom includes antemortem inspection and may cover only part of a particular plant's operations and products.

Official supervision over plants engaged only in intrastate commerce and over food products moving only intrastate, even though originating in federally inspected plants, has remained a function of the State and local governments. An estimated 50 percent of the Nation's processed poultry remains intrastate and is not subject to the Federal Food, Drug, and Cosmetic Act.

State and local governments have adopted varying laws and regulations concerning poultry hygiene (24). Some have not proved to be completely effective, either because they do not cover all major factors or because of a lack of uniformity in requirements, interpretation, or enforcement by jurisdictions in respective shipping and receiving areas. Virginia and Texas have recently initiated voluntary inspection-for-wholesomeness services to poultry processing plants. However, California is the only State which has a mandatory poultry inspection service, and actual inspection in California is conducted by licensed plant owners or employees.

Federal Legislation

In 1957 Congress enacted Public Law 85-172, the Poultry Products Inspection Act. Major items in this bill are:

1. Mandatory inspection by the Department of Agriculture of all poultry processed in plants engaged in interstate or foreign commerce, inspectors to be employees of the Department or designated State employees, and all expense

Home Safety Activities

Increasing numbers of State and local health departments are recognizing that the prevention of accidents in the home is a matter for their concern.

This conclusion, reported by the National Health Council in their 1956 Home Safety Inventory, is based on a comparison with a survey undertaken by the American Public Health Association in 1955.

Only a very small percentage of the health departments consider their present programs adequate, but the wide variety of activities reported by different departments reveal a potential for extensive developments in the future.

Activities mentioned, in order of descending frequency, include assisting other groups in planning their programs, inservice training for their staffs, showing films, releasing news to the press, meetings, coordinating various programs within an area, exhibits, radio and television programs, workshops, institutes and conferences, demonstrations, research, inspections for hazards, surveys for injuries, and courses for baby sitters.

A most encouraging trend, the National Health Council said, is the extent to which local health departments are reaching directly into homes. Furthermore, almost all activities

are directed mainly to the family as a whole. Two-thirds of all health units reporting indicated that their activities were part of established long-range programs.

A healthy trend is evident, the council affirmed, in the degree to which health units are cooperating with other organizations, and in the emergence of the health department as a resource in home safety.

The Home Safety Inventory revealed several weaknesses in health department programs. Few were found to be directed specifically to preschool children and the aged, in whom accidents take their largest toll. Perhaps the greatest defect, the council said, is that most programs were determined by the program directors' felt needs or by a prescribed pattern rather than by the actual needs in the community.

The council's report concludes that "the need for positive leadership in home safety on the community and State level is a definite 'must.' Because of the health departments' awareness of the problem, the skill of their technical personnel, and their resources as an official agency, they are in a unique position to provide leadership and direction in preventing accidents in the home."

and regulations will be required to prevent such deliveries.

4. Irrespective of Federal inspection programs, State and local health departments have basic responsibility for investigating foodborne disease outbreaks attributed to poultry and poultry products and disease outbreaks among poultry plant employees, and for corrective and preventive measures.

5. Many of the public health problems associated with the processing, distribution, and consumption of poultry require research and related field investigations by health department personnel, who can plan and carry out studies correlating all essential factors.

Summary

Current methods of production and distribution of poultry and poultry products pose health and consumer problems which emphasize the need for effective, uniform poultry hygiene programs. These programs should include antemortem and postmortem inspection of poultry for wholesomeness, and supervision of sanitation in the processing and distribution of poultry and poultry products. Continuing research and field investigations will be needed to delineate health hazards associated with the processing and consumption of poultry, and to develop more effective health and consumer safeguards.

The Federal Government can provide substantial assistance to the States in poultry hygiene. The Public Health Service develops program guides and training aids, carries out and supports research and investigations, conducts training, and provides technical assistance with respect to State and local poultry sanitation. The Food and Drug Administration inspects processing plants which ship interstate, and poultry and poultry products in the channels of interstate commerce. The U. S. Department of Agriculture now provides a voluntary, industry-financed poultry inspection service; Congress has enacted a law to provide mandatory Department of Agriculture inspection in all poultry processing plants engaged in interstate commerce. But in the final analysis, State and local governments are confronted with a large part of the responsibility

for establishing and maintaining effective, uniform poultry hygiene programs.

erally accepted as a more than satisfactory substitute for the heated toxin (10), and the intradermal skin reaction gives an index to the expected local and systemic reactions from a large dose of diphtheria toxoid.

A carefully measured 0.10 cc. of the dilute Schick toxin was injected intradermally in the left forearm, and the same amount of the control toxoid was injected into the right forearm after both surfaces had been prepared with alcohol.

For administrative reasons, the tests were read at 48 or 72 hours rather than at 96 or 120 hours as is commonly recommended when a control test is not used (11), and reactions were recorded in terms of actual measurement of the greatest diameter of induration at both the test and control sites. Test reactions of 10 mm. diameter or more, which were more than twice the size of the control reaction, were considered positive. To allay unnecessary anxiety, each child was given a printed interpretation of his particular reaction to the test, and the tester individually discussed the significance of each positive and allergic (control positive) reaction with the student.

While it is recognized that the use of dilute diphtheria toxin and toxoid for the testing actually gives subjects a small amount of immunizing antigen, sufficient to produce immunity in borderline susceptibles and probably cause a significant rise in antibody titer in immune subjects (12), it was not deemed feasible in this study to attempt to evaluate this effect.

To obtain comparable figures for older age groups, the test was also offered to, but not urged upon, the school faculty and lay personnel assisting with the testing. For each person tested the following information was obtained:

name, school, sex, race, birth date, and life-long residence in Montgomery County.

Information as to previous diphtheria immunization was not requested because of the large error in reporting to be expected from such a group as demonstrated by Geiger and associates in their San Francisco study of 1947-48 (13). It was further thought to be unnecessarily time consuming to seek such information from previous school medical records.

Schick Test Results

In the 9 schools with a total enrollment of 1,862 in the senior classes, 1,286 students were tested. Of these, 102, or 7.9 percent, had positive reactions (table 1). This figure is considerably lower than has been reported in similar age groups by other investigators (14-19). An additional 64, or 4.9 percent, had reactions of less than 10 mm., but the majority of these were of less than 4 mm. Since readings were taken at 48 or 72 hours, these probably represented local reaction to the trauma of injection rather than true mild reactions to the toxin, as there was an even greater number of similar minor reactions at the control site.

Of the 110 adults tested, 42, or 38 percent, were positive. This figure approximates those reported in naval recruits (20, 21), in soldiers (10, 22), and in medical students (14). All of these studies, however, dealt primarily with young adults. Sensitivity reactions were more frequent among the adults, as was to be expected, and the severity of such reactions was much greater (14, 16). In at least 3 instances in this study, adults with positive reactions still complained of pruritus and induration 2 months after the testing.

Diphtheria Immunity Status In Montgomery County School Seniors and Adults

JOHN B. ATWATER, M.D., and
WILLIAM J. PEEPLES, M.D., M.P.H.

DIPHTHERIA, once primarily a disease of infants and young children, has been increasing among adults and teen-aged children over the past 20 years (1-4). The shift in age-specific morbidity rates can be traced to markedly decreasing exposures to virulent *Corynebacterium diphtheriae*. The almost universal artificial immunization of infants and children has resulted in less frequent natural immunity among adults.

Somewhere between the adult and the child, however, lies a zone where the protection of unreinforced early immunization begins to wear off. Outbreaks of diphtheria in Detroit, Mich., Albuquerque, N. Mex., and South Carolina in the fall of 1956, while this study was still in the planning stages, pointed up the importance of continued awareness of the disease as a public health problem (5, 6). It also re-emphasized the value of current data on the relative immunity of various population segments in anticipating and preventing outbreaks.

In this study we undertook specifically to determine the relative immunity to diphtheria of the young adult population in an area where only 2 cases, both in white men in their early twenties, have been reported during the preceding 2 years. The study was conducted in Montgomery County, Md., during January and February 1957.

The county, principally a suburban residential center, is northwest of the District of Columbia and has an area of about 525 square miles. Its population, growing at a prodigious

rate in the postwar period with the influx of Government workers, is nearly 300,000. Of these, 6 percent are Negro. The county has the highest per capita income in Maryland.

Information gathered at the time of preschool conferences over the past 4 years reveals that about 92.5 percent of Montgomery County children have been actively immunized against diphtheria prior to registering for school, and the remainder are almost all given primary immunizations at this time (7). However, because of the large population influx, the inadequacy of transferred school health records, and basic doubt as to the duration of immunization in infancy and early childhood (8), the status of children finishing high school has been heretofore unknown. With the approval of the Montgomery County Medical Society and the superintendent of schools and the aid of the Maryland State Department of Health, the Montgomery County Health Department planned to give Schick tests to all 12th grade students in the county's nine high schools.

Procedure

Several weeks prior to the testing in the schools, each student was given a letter explaining the objectives of the testing program and the significance of the individual reactions, and requesting his parents' permission to give the Schick test. The response to the letter varied from 65 percent to 100 percent of the enrollment in different schools.

The actual testing and reading of the reactions was done by a single health department physician. The antigens used, obtained from the biologic laboratories of the Massachusetts Department of Public Health, consisted of diluted diphtheria toxin (0.02 MLD per 0.1 cc. dose) and purified diphtheria toxoid (0.008 Lf per 0.1 cc. dose) for use as the biological control.

Purified diphtheria toxoid was used in the control test to eliminate pseudoreactions caused by heated diphtheria toxin when used as a control. Possibly the heating process used in destroying the diphtheria toxin so alters the other proteins present that they are no longer capable of causing the reactions of the unheated material (9). The amount of toxoid used in each 0.1 cc. dose, though somewhat empirical, is gen-

were referred to their private physician for immunization at his discretion. Because of increased sensitivity to diphtheria toxoid and the questioned significance of a single Schick test in an adult as an indication for toxoid administration (14), adults were cautioned about the possible consequences of requesting immunization and were advised to consult with their physician and to follow his advice. Approximately 2 months after completion of the testing program, a survey of all Schick positive students revealed that only 43 of 102 had contacted their doctors, and 27 of these had received immunizations. In addition, it is known that at least 7 of the adult group received toxoid.

Of 61 Negro students tested, 6, or 9.8 percent, had positive reactions. This is not significantly different from the 7.8 percent positive rate found in 1,225 white students. The reactor rate for all male students was 8.9 percent and for females 7.0 percent (table 2); however, this difference is of doubtful statistical significance.

In the adult group, the reverse was true; males 35.8 percent, females 40.3 percent. It is felt that the relatively increased immunity of the adult male over the female is due to the fact that the males tested were, in general, younger than the females.

Analyzing the reactor rates by age (table 3), a definite rise in the reactor rate with increasing age is evident. It must be recognized, however, that the spread of ages was heavily concentrated in 17- and 18-year olds, with 60 percent and 23 percent, respectively, of the total tested falling in these age groups.

The decreasing levels of immunity with increasing age, evident in this study, is the antithesis of that reported in school children in Baltimore in 1928 (17), and in New York in 1921 (23), when immunity to diphtheria was principally due to natural exposure to *C. diphtheriae* rather than having been artificially produced.

Because of the marked differences in socioeco-

conomic factors between urban and rural sections of Montgomery County, a higher degree of immunity was anticipated for the urban area with its greater availability of medical supervision. Actually, however, the rate of immunity in the 3 largest schools serving the urban segment of the county is insignificantly lower than that in the remaining 6 schools in the more rural areas, which included the 1 all Negro school with the highest rate of any. On the other hand, the spread between the two largest schools with apparently similar population groups was from 6.2 percent to 9.2 percent positive reactors.

To the question, "Allowing for up to 6 months absence, have you always lived in Montgomery County?" 870 students (68 percent) and 100 adults (91 percent) answered negatively. There was no significant difference between the answers of the Schick reactors (students, 65 percent; adults, 90 percent) and the nonreactors (students, 68 percent; adults, 91 percent). This indicates that the marked immigration into the county has not introduced a new susceptible group into a relatively immune population, as has been demonstrated before some epidemics (23).

Conclusions

The principal conclusion to be drawn from the data is that regardless of whatever minor differences in immunity levels among the students might occur on the basis of age, sex, race, length of residence, or rural-urban location, the Schick reactor rate in Montgomery County high school seniors is low. It compares quite favorably with the 23 percent reported in San Francisco (13), and 17 percent in York, Pa. (8).

The senior high school population, therefore, is quite well protected against diphtheria and the occurrence of more than sporadic cases is unlikely. The adults in the school population, on the other hand, are significantly less immune. In addition to the annual evaluation of immunization among preschool children, it might be well to sample regularly, at perhaps 5-year intervals, the diphtheria immunity of the teen-aged groups and young and middle-aged adults.

Such periodic evaluation may well evidence that since infant and preschool immunization

in this particular community is accepted practice, the facilities and efforts of the health department and medical profession should be directed toward maintaining high levels of immunity in the adult population.

In considering this possibility we must remain aware of the high levels of sensitivity to diphtheria toxoid. Edsall and associates report on the use of minute amounts (1 to 2 Lf) of highly purified diphtheria toxoid in combination with tetanus toxoid (25). Such combination has been used by the Armed Forces for approximately 3 years and has recently become commercially available as "tetanus-diphtheria toxoid, for adult use."

It is probable that because of the low incidence of cases of diphtheria and, therefore a decreased incidence of carriers of virulent diphtheria organisms, active, natural immunization is not occurring with any great frequency. The high degree of immunity demonstrated probably represents a carryover of significant protection from preschool immunizations. Immunization in the adult population, however, when performed was done with antigens, presumably less effective than those now available, and the lack of reinforcing exposures to the organism may be of greater importance.

Summary

In January and February 1957, 1,286 Montgomery County, Md., 12th graders and 110 adults were given Schick tests with control tests. The Schick positive rate for the students was 7.9 percent and for the adults, 38 percent. No statistically significant correlation was found for race, sex, or residence.

The results suggest the need for periodic sampling of diphtheria immunity among teen-aged and adult segments of the population.

London Seminar in Health Education

An international seminar on the principles, methods, and media of health education was held in London, England, April 22-25, 1958, under the sponsorship of the Central Council of Health Education.

The program covered the philosophy and practice of health education through theoretical lectures, group discussions, and practical demonstration of techniques. Scheduled subjects were planning the program, choosing the methods, selecting the means, use of equipment, and mass media in health education.

Comparison of CF and HI Tests on Psittacosis-LGV Serums

MATTHEW A. BUCCA, Ph.D.

WITHIN recent years, public health laboratories have received an unprecedented number of requests for the laboratory diagnosis of specimens from patients with suspect infections incriminating members of the psittacosis-lymphogranuloma venereum (LGV) group of viruses. Since most of the laboratories are not equipped to prepare their own psittacosis antigens for the performance of complement fixation (CF) tests, it has been necessary to rely upon commercially available sources for their supply. It has also been the practice, and at times the necessity, to substitute LGV for psittacosis CF antigens in tests on serums from cases of psittacosis on the basis that one is dealing with a group-specific antigen-antibody reaction. Meyer (1) stated that half of his serums positive by psittacosis CF test exhibited no reaction with lygranum antigen dosages indicated on the label. Volkert and Christensen (2), however, concluded from their data that both antigens in two unit dosages may be utilized for routine testing. The present study represents a comparison of three tests using psittacosis and LGV antigens on individual human serums.

Methods

The psittacosis antigen (3) consisted of heavily infected allantoic fluids which were phenolized and subsequently lyophilized after

concentration to one-fifth the original volume. Control antigen was prepared in the identical manner using normal embryonated eggs of the same age and batch.

Lygranum CF antigen was purchased from commercial sources, and the control antigen was the one accompanying the viral antigen.

The CF test for this study was that described by Sigel and co-workers (4). Both psittacosis and lygranum CF antigens were titrated by the block technique with ornithosis positive serum and two units used in the respective tests. Complement was added to the antigen-antibody system in a dosage of 1.8 to 2.0 units. All test serums were preliminarily absorbed with packed sheep erythrocytes and then inactivated at 56° C. for a period of 30 minutes before testing.

The psittacosis hemagglutinating antigen was also prepared from infected embryonated eggs. The infected allantoic fluid was centrifuged at 5,000 × gravity for 1 hour and the supernatant fluid, which served as the hemagglutinin, was stored at temperatures below -30° C. The hemagglutination-inhibition (HI) test was performed according to the method of Hilleman and co-workers (5, 6). All serums for this test were first absorbed with murine erythrocytes and then inactivated at 56° C. for 30 minutes.

Results

One hundred and six "negative" serums were selected to ascertain the baseline reaction of the HI test. Selections were based on a series of preliminary tests performed on serums received in the laboratory showing negative CF reactions in dilutions of 1:2 when tested with psittacosis

Dr. Bucca is chief, Viral and Rickettsial Reagents Unit, Diagnostic Reagents Section, Laboratory Branch, Communicable Disease Center, Chamblee, Ga. The work was performed at the Virus and Rickettsia Section, Montgomery, Ala.

Table 1. Nonspecific inhibition of serums by psittacosis HI test

Serum dilution	Number	Percent
<1:16	30	28.3
1:16	64	60.3
1:32	12	11.5
1:64	0	0

and lygranum CF antigens. These serums were also found to be negative by CF tests for certain members of the neurotropic group of viruses routinely tested in the diagnostic laboratory.

It may be seen from table 1 that nonspecific inhibition may occur in this test in serum dilutions through 1:32. Most of the hemagglutinin inhibitions appeared in serum dilutions of 1:16. A serum dilution of 1:64 must, therefore, be used for the baseline reactivity to avoid nonspecificity.

A total of 103 positive serums were tested for the comparative test series. Most of these

serums (87 percent) were taken from patients presenting a clinical history of, or exposure to, members of the psittacosis-LGV group of viruses (ornithosis and lymphogranuloma venereum). The results of the three serologic tests performed on the same serums are shown in tables 2, 3, and 4.

It is apparent from table 2 that psittacosis CF antigen was able to detect a larger number of positive serums than lygranum CF antigen. Ten of the serums (9.7 percent) showed some positive titer with psittacosis CF antigen when lygranum CF antigen was unable to react at the lowest dilution of serum tested (1:2). Thirty-six (34.9 percent) of the serums elicited the same titer when tested with both CF antigens. Higher titers with psittacosis CF antigen were obtained with 61.2 percent of the serums as compared with lygranum CF antigen tested on the same serums, whereas only 3.9 percent of the serums gave higher titers with lygranum antigen.

Table 2. Number of serums reacting to psittacosis and lygranum CF tests

Psittacosis CF Titers

Serum dilution	<1:16	1:16	1:32	1:64	1:128	1:256	1:512	1:1,024	Total
1:2	1	10	3						14
1:4	1	11	5	6	2				25
1:8		5	4	5	3	2			19
1:16			2	3	10	4			19
1:32			1	5	6	1	2		15
1:64				1	2	4	1	1	9
1:128							1	1	1
1:256							1		1
Total	2	26	15	20	23	11	4	2	103

Table 4. Number of serums reacting to psittacosis HI and lygranum CF tests

		Psittacosis HI Titers							Total
Lygranum CF Titers	Serum dilution	<1:16	1:16	1:32	1:64	1:128	1:256	1:512	
	<1:2		3	2	1	2	1	1	10
	1:2	2	14	6	2		1		25
	1:4		7	4	4	3	1		19
	1:8		2	1	7	8	2		20
	1:16			2	5	6	3	1	17
	1:32				1	4	3	1	10
	1:64								0
	1:128							1	1
	1:256								0
	1:512							1	1
	Total	2	26	15	20	23	11	4	103

From tables 3 and 4 one observes that an equal number of serums (60) showed positive HI titers (considering the baseline titer of the HI test to be 1:64 or higher) from both the psittacosis CF and lygranum CF groups. Five of the serums (4.9 percent) exhibiting no reaction with lygranum CF antigen in dilutions of 1:2 or higher elicited HI titers of 1:64 through 1:512. More serums (33 percent) tested with lygranum CF antigen in low dilutions (up through 1:8 dilution of serum) gave positive HI titers than serums tested with psittacosis CF antigen (18 percent) in the same dilution range. Of the 93 serums which were positive by both psittacosis CF and lygranum CF tests, only 55 (or 59.1 percent) were positive to the psittacosis HI test.

Discussion

The results presented above indicate that a nonspecific reaction may be obtained in the psittacosis HI test in serum dilutions through 1:32. At a serum dilution of 1:32, 11.5 percent of the 106 serums tested showed this type of reaction. Hilleman and co-workers (5) have indicated from a smaller group study that human serum titers of less than 1:40 are not considered significant when tested with meningopneumonitis hemagglutinating antigen. Studies conducted by Ephrati-Elizur and Bernkopf (7) show that 6 percent of their apparently normal serums reacted nonspecifically in dilutions of 1:40 and 2 percent in dilutions of 1:80. They, therefore, considered HI titers above 1:80 as falling outside of the normal

range of nonspecificity. It should, however, be pointed out that this unfavorable property of the HI test may not necessarily invalidate the application of this test to diagnostic procedures. The serologic criterion of an infection is generally taken as a fourfold or higher increase in titer of the convalescent phase serum over the acute phase specimen. Although individual serums elicit considerable variations in the nonspecific property, the demonstration of a rise in HI antibody with paired serums may provide significant diagnostic information.

Meyer and Eddie (8) state that LGV antigens from any source are unsatisfactory for the serodiagnosis of psittacosis infections and that only psittacosis antigens should be utilized in the CF test. A large number of our reactive serums were derived from patients with clinical histories indicating infections of the psittacosis-LGV group or presenting a history of exposure to birds. Our results verify the fact that the psittacosis antigen generally exhibits a higher sensitivity than the lygranum antigen in serums with positive psittacosis CF tests.

Summary and Conclusion

Three tests were compared for the detection of antibodies to the psittacosis-LGV group of viruses.

The psittacosis HI test exhibits nonspecific reactions in serum dilutions through 1:32. This places a limitation on its practical application except where a significant antibody rise in paired serums can be demonstrated.

Only 59 percent of the serums positive by both psittacosis CF and lygranum CF tests were also positive by the psittacosis HI test.

With the current techniques employed, the psittacosis CF antigen reacts with a larger number of serums and in general gives higher titers than the lygranum CF antigen.

Local Health Departments and Rehabilitation

Local health departments with trained and experienced staff would be immensely helpful in all areas of service to the handicapped, according to the conclusions of a 1956-57 study of rehabilitation services for the deaf and hard of hearing in Metropolitan Boston. The study was conducted by the Rehabilitation Council, United Community Services of Metropolitan Boston.

Lack of adequate local public health services is basic to many of the problems of availability and use of rehabilitation services, the council concluded. They mentioned these problems in particular: hearing testing in parochial schools, followup of screening test failures, development of ancillary services in suburban and rural areas, and adequate speech reading and auditory training facilities in public schools.

Many of the findings of their study, the council pointed out, are applicable to all the handicapped.

Variation in Three Staphylococcal Typing Phages

JOHN E. BLAIR, Ph.D.,
and E. T. BYNOE, Ph.D.

A standard set of staphylococcal typing phages is now used in practically all laboratories where a staphylococcal typing service has been established. Comparison of the phage patterns encountered in different laboratories is valid only to the extent that the phages used in those laboratories have remained stable and have retained their original patterns of lytic activity. This is especially important when one attempts to determine the geographic distribution of strains of *Staphylococcus aureus* showing a specific phage pattern. It is conceivable that although the same strain might be encountered in several different laboratories, it would not be regarded by some laboratories as being identical if variation had affected the lytic patterns of the phages concerned.

That variation in patterns of lytic activity may occur was demonstrated by Wahl (1), who noted that from phage 44A, which has a rather limited lytic spectrum, a mutant phage developed which exhibited a wide range of activity. The mutant was designated as "phage 68."

We have obtained evidence which suggests that variation in lytic activity has taken place in certain staphylococcal typing phages that are currently being used in the United States. The phages involved are those designated as "52," "42B," and "44A."

Dr. Blair is head of the division of bacteriology, laboratories division, Hospital for Joint Diseases, New York City, and Dr. Bynoe is chief of the bacteriology laboratories, laboratory of hygiene, Department of Health and Welfare, Ottawa, Canada. They represent the United States and Canada on the International Committee on Staphylococcus Phage Typing, and their laboratories are the central reference laboratories for staphylococcal phage typing in their respective countries.

Phage 44A appears to have undergone variation in the direction of a wide host range, in a manner comparable to that observed by Wahl. It often occurs in the phage pattern of strains of staphylococci in any of the broad phage groups, and thus appears to be of little differential value.

Soon after the report by Bynoe, Elder, and Comtois (2) of the existence of a strain of *S. aureus* which was susceptible only to the recently described phage 81, it was found that apparently similar strains isolated in the United States were lysed by phages 52 and 42B as well as by phage 81. We suspected that this could probably be attributed to the fact that the phages 52 and 42B employed in laboratories in the United States had undergone some variation in lytic activity in the direction of a slightly wider host range. In most instances these phages had been supplied by Dr. Blair.

To determine whether variation in lytic activity had occurred, we examined a number of strains of *S. aureus*, isolated both in Canada and the United States, which were known to be susceptible to phage 81. The stock phages and propagating strains of our laboratories were exchanged and the following preparations were made in each laboratory: Laboratory of Hygiene ("LH") phages were propagated on LH strains of *S. aureus*; LH phages were prepared on Hospital for Joint Diseases (HJD) strains; HJD phages were propagated on LH strains; and HJD phages were prepared on HJD strains. The cultures to be examined were then typed in the usual manner with each of the four phage preparations.

The results obtained in both laboratories showed essentially mutual confirmation. Canadian strains of *S. aureus* that had been lysed only by the LH stock phage 81 showed only the pattern 81 when typed with LH phages prepared on either LH or HJD propagating strains. When typed with HJD phages prepared on either LH or HJD propagating strains, they showed the pattern 52/42B/81. Strains isolated in the United States that had originally shown the pattern 52/42B/81 with the HJD stock phages were lysed only by phage 81 when typed with LH phages prepared on either LH or HJD propagating strains. When typed with HJD phages prepared on LH or

HJD propagating strains, these strains showed the pattern 52/42B/81.

It seems clear that phages 52 and 42B, as maintained in the laboratory of the Hospital for Joint Diseases, had undergone variation to the extent that they were able to lyse cultures of "type" 81. Variation apparently has not gone beyond this point, for both phage 52 and phage 42B have appeared only in other patterns in which they might normally be expected to occur.

The cultures, stock phages, and propagating strains from both laboratories were submitted to Dr. R. E. O. Williams in the Central Reference Laboratory in London, who examined them in a manner similar to that described above and in a personal communication reported confirmation of our results.

Bynoe and his associates have reported that phage 80, which was developed in Australia by Rountree and Freeman (3), appears to be closely similar to phage 81, and that cultures of *S. aureus* which are susceptible to phage 81, are nearly always lysed also by phage 80 (2). This has been the experience in the laboratory of the Hospital for Joint Diseases.

There would appear to be little question that the strains of *S. aureus* which now are being widely encountered in Canada and the United States and which have been reported, respectively, to show the patterns 81 or 52/42B/81

are identical. In the interest of uniformity of reporting and to remove any confusion that might exist in the minds of the readers of the literature as to the identity of these strains, the authors propose that such strains now be designated as 80/81, the designation given them by the International Typing Reference Center at the Central Reference Laboratory.

To insure results that are more nearly comparable to those obtained at the Central Reference Laboratory, Dr. Blair has obtained from Dr. Williams new specific lots of phages 52, 42B, and 44A, which he plans to include in sets of phages for future distribution and to send to those laboratories in the United States where a phage typing service is now in operation.

PHS Exhibit

Sanitary Engineering Center Program

An exhibit of the Robert A. Taft Sanitary Engineering Center of the Public Health Service shows major programs of environmental research. The central panel is flanked by four others, for air, water, radiation, and food, respectively.

The displays include animated and still graphics, models, samples, literature, and some equipment in operation.

Specifications: Floor space 20' by 8'. (Can be used with different arrangements of the five units.) Operates from one or two 110-volt a. c. outlets. Shipping weight, 1,200 lbs. The setting-up requires two men. Available by special arrangement only with the Director, Robert A. Taft Sanitary Engineering Center, Public Health Service, Cincinnati 26, Ohio.

Poverty, Pica, and Poisoning

J. EDMUND BRADLEY, M.D., and SAMUEL P. BESSMAN, M.D.

A RECENT study of 333 children living in an old, congested, low-income area of Baltimore, Md., showed that 44.4 percent of these children had abnormal blood lead values of 0.05 mg. percent and higher (1). The children were selected at random from those brought to the pediatric clinics of the University of Maryland Hospital for health supervision or for complaints other than those usually associated with lead poisoning.

Since the history of pica (eating of nonfood material) was found in 69.6 percent of the children, the source of lead apparently was paint chewed from surfaces of wood or plaster or particles of paint swallowed after it had flaked from the surfaces.

Samples of paint were collected from typical homes and the lead content determined. The lead content in each sample was in excess of the recommended 1 percent of the total weight of the contained solids (2).

The majority of the children apparently swallowed paint from indoor surfaces. However, others may have eaten paint which had peeled from exterior walls. The interior of the home of one child with lead poisoning did not have toxic amounts of lead on its painted surfaces, but it was learned that the child sat on the stoop outside and ate particles of paint fallen from the exterior walls. These contained toxic amounts of lead.

Dr. Bradley is professor and head of pediatrics, and Dr. Bessman is associate professor of pediatrics, University of Maryland School of Medicine. A grant-in-aid from the Department of Health, Education, and Welfare supported the study described in this article.

Pica as the source of lead was also supported by the lack of abnormal blood lead values in infants under 10 months of age. However, the increased incidence of abnormal values beginning at 10 months of age continued through the third year of life and then declined. This age distribution corresponds to the period when the child is confined to the home, has greater need for oral gratification, and in crowded situations has fewer controlled interest opportunities. Further support for pica as the source of lead intoxication is found in current studies by Dr. J. E. Bradley and R. S. Mosser of blood lead values of children in different socioeconomic strata. The data obtained suggest that the mean values of the lower group will exceed many fold the mean values of the middle and upper groups.

Contributing factors to this high incidence of lead intoxication seems to be related directly to environment. First, these children live in houses where lead-containing paint, used many years ago, is now flaking and peeling from the surface. Second, there seems to be widespread ignorance or disregard of the hazards to the child through the ingestion of these particles. Despite vigorous education campaigns which have been conducted by the public health department in Baltimore, many parents continue to accept pica as a harmless manifestation of normal infantile development. Third, crowded conditions within the home, and in many instances the absence of supervision by adults who may be obliged to leave the children to earn a living, allow the infant and preschool child opportunity to eat toxic material without restraint.

The main hazard of lead poisoning in a child

is lead encephalopathy. The frequency of lead encephalopathy is unknown, since only a few communities require reports of these cases. The incidence is suggested from the report that 538 Baltimore children were admitted to Baltimore hospitals with lead encephalopathy from January 1, 1931, to January 1, 1956 (3). Lead encephalopathy, despite recent advances in treatment, continues to result in neurological sequela, mental retardation, or death (4,5).

The observations in the Baltimore study suggest that there is a high incidence of lead poisoning in other metropolitan areas where slums exist and where paint contains lead. The study also suggests that physicians need to be constantly aware and alert to the symptoms of lead poisoning in children.

Since this disease is essentially environmental, preventive measures are possible. This will require the cooperative effort of physicians, nurses, and social workers of municipal health and welfare departments who will warn par-

ents constantly of the seriousness of pica in children.

Legal Criteria for Evidence of Intoxication

A bill setting forth the legal significance of findings from alcoholic intoxication tests of drivers on trial in the District of Columbia became law March 4, 1958. The legislation eliminates a previous need for expert witnesses to explain the legal ramifications of test results.

If the defendant's blood has 0.15 percent or more alcohol by weight, or an equivalent proportion of alcohol in 2,000 cubic centimeters of his breath, he is presumed to be intoxicated. Alcohol equaling 0.20 percent by weight in the urine has the same legal significance.

Percentages of 0.05 or less in the blood or breath and 0.08 or less in the urine are proof of sobriety; and alcohol levels between 0.05 and 0.15 in the blood and breath and between 0.08 and 0.20 in the urine constitute relevant evidence but neither proof nor disproof of sobriety or intoxication.

Drivers are not obligated to submit to the tests, the results of which apply when they are tried for driving while intoxicated, for negligent homicide, or for manslaughter.

Only a physician acting at the request of a police officer may withdraw a blood sample for testing. The defendant may request that his own physician conduct additional chemical tests. Results are available to the tested person on request.

Rat, Flea, and Murine Typhus Recurrence Following Eradication Measures

WILLIAM W. SMITH, Ph.D.

AN EXPERIMENTAL attempt to eradicate murine typhus was made in the rural southeastern quarter of Grady County, Ga., between July 3, 1953, and May 4, 1954. The experiment was considered a success and has been reported by Mohr and Smith (1).

The chief eradication measures used were intensive poisoning of commensal roof and Norway rats, *Rattus rattus* (Linnaeus) and *Rattus norvegicus* (Erxleben), and applying 10 percent DDT dust in rat runs to reduce the numbers of oriental rat fleas, *Xenopsylla cheopis* (Rothschild). Though lack of time for extensive studies and application of special treatments made it impossible to eliminate rats completely at about 5 percent of the farms in the experimental area, it was believed that eradication of murine typhus would not require complete elimination of rats and oriental rat fleas.

For 3 years after the eradication program, the experimental area was inspected periodically to determine the rates at which commensal rats, rat fleas, and murine typhus reestablish themselves. The results of these inspections are reported here.

Methods and Procedure

During the period July 13 to August 5, 1954, a preliminary inspection was made of 306 premises closest to the 5.5 percent from which it had not been possible to eradicate all rats. More extensive inspections were made annually during the months of March through May in 1955, 1956, and 1957. It was not possible each

year to inspect every one of the premises originally inspected and grouped according to infestation status under the eradication program. Each annual inspection, however, covered a representative number of premises in each of the three groups that had been set up under the eradication program (table 1).

The farm premises were examined for signs of rats such as fresh droppings, burrows, trails, and gnawing. Occupants were questioned as to whether or not rats were present. If there was doubt as to the existence of an infestation, dust patches were used and the premises were reinspected until a definite decision could be reached.

Unbaited No. 0 steel traps were set in runs wherever it appeared that rats might be caught. Rats obtained alive were brought to the laboratory where they were identified, sexed, killed by bleeding from the heart, and brushed and searched for ectoparasites. Blood serums from these rats were sent to the Communicable Disease Center Virus and Rickettsia Disease Laboratory in Montgomery, Ala., where they were tested by complement fixation for the presence of murine typhus antibodies. Rats found dead in the traps were identified and recorded, but they are excluded from discussion and data presented in this paper.

Dr. Smith was, until recently, an entomologist with the Communicable Disease Center, Public Health Service, at the Newton Field Station, Newton, Ga. He is now assistant professor of entomology and assistant director of pest control at the University of Florida, Gainesville.

Although eradication measures were employed until May 4, 1954, many premises had been cleared of rats before that date. For purposes of discussion, the 1955, 1956, and 1957 inspections are considered to have been completed, respectively, 1, 2, and 3 years after the eradication program ended.

Rat Reinfestations

The preliminary inspections made in the summer of 1954 showed that 16 (5.2 percent) of the premises nearest the farms at which it had not been possible to eliminate rats had become infested again. Practically all of the 306 premises inspected at that time were within three-fourths of a mile of such farms.

The results of the last three annual inspections are shown in table 1. Of the premises

cleared of rats under the eradication program and inspected each year, 70.6 percent remained uninfested at the end of the first year (1955), 67 percent at the end of the second year, and 58.3 percent at the end of the third year. In 1955, 25.4 percent of the premises inspected again had rats, and another 4 percent had become infested but were clear of rats at this inspection. In 1956, 17.2 percent of the premises inspected were reinfested, while 15.8 percent had had rat infestations since the end of the eradication program but were uninfested at the time of inspection. Inspection in 1957 showed 29.9 percent reinfested, and another 11.8 percent which had been reinfested since 1954 but were clear at this inspection.

Premises uninfested at the time of eradication changed little from year to year, as shown by the high proportion of these premises which remained clear over the 3-year period—91.5 percent of those inspected in 1955, 89.4 percent in 1956, and 85.5 percent in 1957 (table 1).

The greatest changes of infestation status occurred in the small group of infested premises which had not been cleared of rats by eradication efforts. In 1955, 55.2 percent of the premises inspected in this group were uninfested at the time of inspection. By 1956, the percentage of premises inspected that had been clear of rats at some time since 1954 had changed to 75.9, and by 1957, to 78.6.

Typhus Antibodies in Rats

Tests of serums from 70 rats trapped immediately after eradication at 28 uncleared prem-

ises showed that 3 rats had typhus antibodies (table 2). These 3 rats came from 2 premises well within the study area. At the end of the first year after eradication, only 1 rat with typhus antibodies was found among the 139 rats trapped from 57 premises. This rat was taken from a farm at the edge of the eradication zone and was believed to have moved in from the adjacent untreated region. At the end of the second year, 4 of 142 rats taken from 41 farms showed typhus antibodies. These 4 rats came from 2 farms, one of which was near the border and the other well within the eradication area. At the end of the third year, none of the 148 rats trapped from 66 farms revealed any typhus antibodies.

Ectoparasite Abundance

Data on ectoparasite infestations of the rats examined from 1954 through 1957 are shown in table 3. In 1955, 1956, and 1957, the percentages of rats examined which were infested with *X. cheopis* were 0.0, 8.5, and 4.1, respectively. *X. cheopis* indexes (average per rat examined) were 0.0, 0.2, and 0.4 for those years. In the same years, the sticktite flea (*Echidnophaga gallinacea*) was the most abundant flea species, with averages of 6, 7.4, and 3.9 per rat examined. The most common mite was *Bdellonyssus bacoti* with annual averages per rat of 7.8, 1.1, and 2.3. The spined rat louse (*Polyplax spinulosa*) was found on 57.5, 62, and 83.2 percent of the rats examined in these years; its annual indexes were 7.2, 6.8, and 9.9, respectively.

Discussion

Two to three months after typhus eradication measures were terminated, about 5 percent of the farm premises which had been cleared of rats during the operational period had become reinfested. All were within 1 mile of rat-infested farms. This relatively high rate of reinfestation, including those premises that had become infested but were clear at annual inspection, increased to 29.4 percent, 33 percent, and 41.7 percent of premises inspected in 1955, 1956, and 1957, respectively (table 1). The reinfestation rate was undoubtedly influenced greatly by the proximity of premises susceptible to rat

¹ Numbers of rats examined for ectoparasites in the years 1954-57 were 34, 139, 142, and 148, respectively, and are identical with numbers of rats trapped each year except for 1954, when 70 rats were trapped (table 2).

infestation to those where some rats remained. Emlen and others (2) found that populations of Norway rats in urban situations recovered at the rate of 2 to 6 percent per month when reduced to as low as 10 percent of their original level.

Reinfestation of cleared premises, again including those that had become infested but were clear at annual inspection, increased very little (by 3.6 percent of premises inspected) between the 1955 and 1956 inspections. Possibly the increase in reinfestation was small in the second year because the emigrant rats were reestablishing colonies in the new situations and had not increased in numbers sufficiently to supply impetus for further extensive emigrations. In the third year, however, reinfestation increased by 8.7 percent (table 1). Emlen and his co-work-

¹ Numbers of rats examined for ectoparasites in the years 1954-57 were 34, 139, 142, and 148, respectively, and are identical with numbers of rats trapped each year except for 1954, when 70 rats were trapped (table 2).

infestation to those where some rats remained. Emlen and others (2) found that populations of Norway rats in urban situations recovered at the rate of 2 to 6 percent per month when reduced to as low as 10 percent of their original level.

Reinfestation of cleared premises, again including those that had become infested but were clear at annual inspection, increased very little (by 3.6 percent of premises inspected) between the 1955 and 1956 inspections. Possibly the increase in reinfestation was small in the second year because the emigrant rats were reestablishing colonies in the new situations and had not increased in numbers sufficiently to supply impetus for further extensive emigrations. In the third year, however, reinfestation increased by 8.7 percent (table 1). Emlen and his co-work-

ers (2) noted in their study that 2 years elapsed before reinfestation occurred in one location where all Norway rats had been destroyed.

Since only one survey of the study area could be made each year, progressive emigrations and reinfestations could be determined only in a general manner. Few premises which were reinfested during the first year were as far as a mile from one of the premises not entirely cleared of rats. The manner and causes of rat migration to new premises were not determined, but in addition to the ecological factors, such as dwindling food supplies and harborage removal, commonly believed to motivate emigrations, inherent wandering tendencies—particularly in roof rats—appear to be influential.

Rural premises which are uninfested by commensal rats are generally incapable of supporting or harboring these rodents. If the farm is a poor one, little or no foodstuff is likely to be available to rats, and the usual small, openly constructed buildings do not afford suitable harborage. Another deterrent is activity constant enough to disturb rats attempting to settle. In the eradication area, rat control measures on farms were rarely extensive enough to prevent reinfestation. In a few cases, however, the intensive efforts of individual farmers apparently accounted for complete freedom from commensal rats, at least for short periods. For these varying reasons, uninfested premises tended to remain uninfested (table 1).

Farms at which rat eradication was impossible were least stable with relation to changes in rat infestation. At the end of each of the 3 years after eradication measures ceased, 55.2 percent, then 75.9 percent, and finally 78.6 percent of inspected premises were free of rats. Smith (3) recorded a natural decline of approximately 65 percent in farm premises infested with commensal rats in neighboring Thomas County, Ga., over the past decade. In addition to the natural environmental factors which would account for part of the decrease in the number of rat-infested farms within the eradication area, it is believed that certain other factors stemming from the typhus eradication program also were contributory. These factors are: (a) individual actions resulting from the creation of desire in the farmer to get rid of rats, and (b) the program's reduc-

tion of the number of rats to the point where differences in age and sex composition prohibited reproduction of those remaining. The latter factor was believed by Emlen and his colleagues (2) to be responsible for the very slow recovery of Norway rat populations which had been reduced to a few individuals.

Complement fixation tests of rat blood serums indicated that antibodies to murine typhus had disappeared from the rats in the eradication area by the end of the first year, although one rat with typhus antibodies was taken at the border adjoining a known typhus-infected premise. Three of the four rats with typhus antibodies trapped at the end of the second year (1956) came from a farm in the heart of the eradication area. This farm had had a roof rat infestation which eradication measures had failed to dislodge. One of the three rats with antibodies taken from this farm was a Norway rat, indicating the possible reintroduction of typhus infection from an outside source. At the end of the next year, no evidence of rat infestation could be found at this farm, possibly because of poisoning attempts by the owner. The fourth rat with typhus antibodies (1956) was trapped at a farm near the southern edge of the experimental region. It had probably emigrated from outside the zone since several other rats taken from the same farm had no antibodies to murine typhus. The supposition that typhus was not being transmitted from rat to rat in the experimental area was further strengthened by the absence of any evidence of previous typhus infection in the rats trapped at the end of the third and final year.

A recently published paper by Smith (4) comparing seasonal prevalence of typhus antibodies in rats with seasonal occurrence of important commensal rat ectoparasites indicates the importance of the oriental rat flea, *X. cheopis*, as the natural vector of murine typhus among rats and the relative unimportance of other common ectoparasites. Prior experience has shown that an average of at least 1 *X. cheopis* per rat trapped usually accompanies successful transmission of typhus from rat to man. No such estimate has been postulated for rat-to-rat transmission, but the averages of 0.2 and 0.4 *X. cheopis* per rat trapped in the experimental area at the end of 2 and 3 years follow-

ing eradication indicate the practical elimination from the area of the hazard to humans of typhus transmission from rats. Although the oriental rat flea and the tropical rat mite infested more rats at the end of the second year than at the end of the first or third years (table 3), this may have been due to weather conditions toward the end of the second year which favored these ectoparasites. In fact, no case of murine typhus in humans is known to have occurred in the typhus eradication area of Grady County since the cessation of eradication measures on May 4, 1954.

Summary

During a 10-month operational period, an attempt was made to eradicate murine typhus fever from the rural endemic foci in the southeastern quarter of Grady County, Ga. Intensive rat poisoning and applications of 10 percent DDT dust to rat-infested farm premises were the chief eradication measures used.

Four extensive inspections were made within the area after eradication measures ceased on May 4, 1954. A preliminary inspection made within 2 months after the eradication program ended indicated reinfestation of 5.2 percent of the farms nearest to those where rats were not completely eradicated. More complete inspections of the farms in the eradication area at intervals of 1, 2, and 3 years after eradication

showed that rats had reinfested 29.4, 33, and 41.7 percent of the farms from which rats had been cleared.

Typhus antibodies were found in 3 of 70 rats trapped in the area immediately after the eradication program. At the end of 1 year, the 1 rat with typhus antibodies among 139 rats trapped was believed to have emigrated from adjoining untreated territory. Four rats of a total of 142 trapped at the end of the second year had antibodies to typhus, while none of 148 rats taken at the end of the third year revealed typhus antibodies. No human cases of murine typhus are known to have occurred in the experimental area since the cessation of operational procedures on May 4, 1954.

Studies on Radiation Hazards Scheduled

A new program to study the hazards of radiation will be initiated in 1958 at the New York University-Bellevue Medical Center through a \$500,000 grant from the Rockefeller Foundation.

According to Dr. Norton Nelson, director of the Center's Institute of Industrial Medicine, who will direct the activities of the program, attention will be given to radiation hazards for the general population as well as to special risks in industrial use.

Domestic Agricultural Migrants in the United States (map and table)

PHS Publication No. 540. 1957. 25 cents.

Prepared as a basis for planning health services, the map indicates the peak demand in 902 counties which were estimated to have 100 or more migrant workers from outside the county at the peak of the normal crop season. The table gives the population of these counties and the estimated number of migrants needed by each.

The basic data were obtained from the U. S. Departments of Labor and Agriculture and were checked by State health agencies.

Urban Fringe Sanitation A selected bibliography

PHS Publication No. 583 (Public Health Bibliography Series No. 18). 1958. By Warren F. Smith. 27 pages. 15 cents.

One hundred annotated references have been prepared to assist sanitary engineering personnel. The bibliography is organized under four subjects: water supply, sewerage, refuse, and planning, with further breakdowns as to administrative, economic, and technical articles for the water and sewerage portions.

Rabies: Methods in Laboratory Diagnosis

PHS Publication No. 568. 1957. By Ernest S. Tierkel and Helen O. Neff. 42 pages; illustrated. 25 cents.

Designed to provide a practical guide for workers concerned with routine rabies diagnosis, this manual presents techniques selected for their simplicity, dependability, and economy.

The subjects cover preparation of suspected tissues for laboratory diagnosis, microscopic examination for Negri bodies and performance of the biological diagnostic test. Information on packing and shipping specimens and regulations covering their transportation plus a sample animal history form and a list of selected readings are included.

Control of Domestic Rats and Mice

PHS Publication No. 563. 1957. By Bayard F. Bjornson and Charles V. Wright. 25 pages; illustrated. 25 cents.

This training handbook describes briefly rodent-borne diseases, such as murine typhus, plague, rat-bite fever, salmonellosis, and rickettsialpox, and discusses identification and biology of domestic rats and mice.

The role of sanitation, including proper storage, collection and disposal of refuse, as well as methods of rodent killing, trapping, rodenticides, and burrow gassing, are emphasized. Simple methods of rat-proofing, formulas for common rodenticides, and methods of controlling rodent ectoparasites are given.

Patients and Personnel Speak

A method of studying patient care in hospitals

PHS Publication No. 527. 1957. By Faye G. Abdollah and Eugene Levine. 33 pages. 30 cents. (Checklist forms for patients and personnel, \$3.00 per 100.)

The technique used successfully by 60 American Hospital Association member hospitals to evaluate their nursing services has been refined and made available in this manual.

The booklet discusses the value of studying patient care, how to get started, the responsibilities of study personnel, and how to tabulate and analyze the data.

Forms for gathering data and a tested checklist on which hospital patients, doctors, administrators, and nursing staffs can state their personal observations of gaps in service are included.

Information Leaflets

GOOD TEETH. *PHS Publication No. 405. (Health Information Series No. 83) Revised 1957. 11 pages. 10 cents.* Gives pointers on dental care for children from infancy through childhood. Discusses the value of fluoridation and tells at what ages topical applications of fluoride should be made.

SIMPLE GOITER. *PHS Publication No. 100. (Health Information Series No. 56.) Revised 1957. Leaflet. \$2.00 per 100.* Describes briefly cause, effect, prevention, and treatment of simple goiter.

GALLSTONES AND GALL BLADDER DISEASE. *PHS Publication No. 99. (Health Information Series No. 58.) Revised 1957. Leaflet. \$3.00 per 100.* Describes gallstones, the symptoms they produce, and emergency treatment. Discusses importance of consulting a physician.

This section carries announcements of new publications prepared by the Public Health Service and of selected publications prepared by other Federal agencies.

Unless otherwise indicated, publications for which prices are quoted are for sale by the Superintendent of Documents, U. S. Government Printing Office, Washington 25, D. C. Orders should be accompanied by cash, check, or money order and should fully identify the publication. Public Health Service publications which do not carry price quotations, as well as single sample copies of those for which prices are shown, can be obtained without charge from the Public Inquiries Branch, Office of Information, Public Health Service, Washington 25, D. C.

The Public Health Service does not supply publications other than its own.

Rehabilitation of the Cardiac

PHILIP R. LEE, M.D.

Dr. Lee introduces a provocative approach to the most common form of disability, one which does not lend itself to the usual process of physical repair or vocational training. Public Health Reports will welcome papers dealing with specific applications of Dr. Lee's philosophy.

REHABILITATION of the cardiac is a complex process, properly initiated by medical, social, psychological, and vocational evaluation of the patient.

The cardiac may be an infant with congenital heart disease, a youngster with acute rheumatic fever, a miner with cor pulmonale, an executive with acute myocardial infarction, a farmer with hypertensive cardiovascular disease, or an elderly housewife with chronic rheumatic heart disease. The various etiological types of heart disease must be differentiated in the light of increasing numbers of therapeutic approaches available. For example, the prophylactic use of penicillin to prevent streptococcal infection in youngsters who have recovered from rheumatic fever has prevented recurrent attacks of rheumatic fever and has thus enabled children to live lives nearer normal.

Impairment and Disability

The patient with heart disease may suffer no disability as a result of his disease or he may be totally disabled. Impairment and disability are often considered to be synonymous, but actually, total disability means the inability to engage in work commensurate with his previous training and his skills and aptitudes, while impairment refers to any structural or functional abnormality. The person who has heart disease may have an impairment of structure or

function without disability, or he may be totally disabled with only a minor impairment.

Heart diseases are often associated with a protracted course often with a gradual cumulative impairment, and with a clinical picture that may be complicated by physical, psychological, social, vocational, or economic dislocations.

There may be a short period of severe physical handicap and total disability, followed by complete functional recovery without disability, as in the case of the patient who suffers a heart attack; there may be a gradual progressive downhill course, as in some patients with chronic rheumatic heart disease; there may be a long period of relatively good health with death due to unrelated causes; there may be chronic ill health followed by complete surgical cure, as in many patients with congenital heart disease; or there may be years of little or no handicap terminated by a year or more of increasing ill health and finally death, as in certain patients with severe hypertension. Between the extremes of sudden death and normal life may occur all varieties of physical and functional impairment, as well as physical, psychological, social, and vocational handicap or disability among patients with cardiac disease.

The physical handicaps of the cardiac are most often a diminished tolerance for exercise, easy fatigue, shortness of breath, swelling of the ankles, or anginal pain. Other less common symptoms may occur as a result of heart disease. Psychological handicaps may be greater than the physical. They are likely to take the form of fear of sudden death, anxiety, depression,

Dr. Lee, who has written a number of articles on rehabilitation, is with the Palo Alto Medical Clinic, California.

overconcern about the heart, hostility or rejection.

Although the great majority of patients with heart disease are able to lead relatively normal lives despite some organic impairment and many are able to work productively in industry, to attend regular school, to labor on the farm, or to carry out the manifold duties of the housewife, any individual with heart disease may be severely handicapped.

Evaluation

Rehabilitation of the cardiac should begin the moment he is stricken. The first step in this rehabilitation is proper evaluation, including assessment of the physical, psychological, social, and vocational status of the patient. This may be accomplished by the family physician without the aid of the social worker, psychologist, vocational counselor, and consultant cardiologist. If any of the latter are required, however, it is the responsibility of the patient's physician to be sure their services are made available.

It has been estimated that for 80 percent of the cardiac patients evaluation and the management of the total rehabilitation program can be carried out by the patient's personal physician, but for 20 percent of the patients a team approach is essential if the patient is to achieve his maximum level of function in society.

The medical examination should include a careful, accurate, and thorough history as well as a complete physical examination and appropriate laboratory studies. The physician should also assess the patient's functional capacity. The patient may be able to perform the ordinary activities of life without distress, or may find it difficult if he is recovering from an acute cardiovascular illness or if he has many psychological problems which alter his subjective response to exercise.

After the physician has estimated the patient's functional capacity, he should evaluate physical and emotional stresses in the patient's daily life to determine if the patient has the capacity to continue his normal activities. Considerable information is now available for this assessment, not only on the energy cost of a variety of activities, but also on environmental

stresses and on the stresses imposed on individuals by their emotional reactions.

Emotional problems are often of greater importance in rehabilitation than the physical limitations imposed on the patient by his disease. The physician can usually determine the major emotional problems if he allows the patient sufficient time to relate the details of his illness, his concerns about himself, his family, job, and future. Occasionally it is necessary to have psychological testing or psychiatric consultation or both.

Of considerable importance in returning a patient to work is the patient's attitude. Jones used a simple method to classify patient's attitudes toward work which he found correlated rather well with success or failure in vocational rehabilitation. The following was his classification. Good: actively seeking employment and cooperative in attempts to help him; fair: willing to work, but doubtful of his ability to do so; poor: not seeking work and maintaining he had difficulty in working; and, bad: obstructing attempts to find him work and claiming his heart made him unfit. Of the patients with a good or fair attitude two-thirds were resettled in productive employment while only one-third of those with a poor attitude and none with a bad attitude were resettled.

If the psychological assets are positive and the patient is strongly motivated, much can be accomplished by the individual, even in the presence of severe organic heart disease. If the patient is not motivated and cannot become so, the physician and other members of the rehabilitation team are likely to accomplish little even if the patient has no physical limitation.

In evaluating the emotional status of a cardiac, especially a child, the patient's family must be considered. Often the family will make the difference between success or failure in rehabilitation. If they are understanding and cooperative they can be of immeasurable aid, but if they are overprotective, fearful, or rejecting, rehabilitation attempts may meet with failure.

Sociologic Factors

The physical and psychological aspects of cardiac rehabilitation have received considerably more attention than have many of the soci-

ologic factors despite the latter's importance in rehabilitation. Limitations placed on many cardiacs by their physicians severely restrict their social opportunities as do the employment policies of many industries and the current interpretation and administration of many of our workmen's compensation laws.

When the social and vocational status of any cardiac is evaluated, the fact that the majority of cardiacs can live relatively normal lives should be kept in mind. The majority who labor in industry, on the farm, in the home, or who attend school are better off continuing in their usual work or habits of life than by radically altering them when no clear-cut indication to do so exists.

Points to be emphasized in the social history are the psychological factors to which may be added family relationships, economic status, housing, and education. In the vocational history, information should be obtained on specific characteristics of the job or work place, operations or activities involved, environmental conditions, wages, group pressures or other social pressures on the job, previous vocational experience or training, skill, adaptability, and interests.

For children, appropriate emphasis must be placed on the family, on the child's intelligence, education, interests, motivation, and potential for future activities. In this instance, skill may be developed and patterns established, whereas in older cardiacs often the only realistic approach is to attempt to restore the patient to his usual habits of life and work.

Individualized Planning

Parallel with the evaluation is the individualization of the rehabilitation program. Although two patients have the same organic defect they will not have the same personality, nor will their habits or environmental stresses be the same. These factors must be considered when giving the patient advice about diet, drugs, physical activity, occupation, recreation, sexual activity, emotional stress, smoking, and the variety of day-to-day problems involved in his rehabilitation.

In what is perhaps the single most important step in the rehabilitation process, the physi-

cian's unhurried discussion with the patient about his disease, the emphasis should be on the more optimistic aspects, particularly regarding prognosis and the ability of the patient to return to a reasonably normal and productive life. The patient should be told in some detail how he can best arrange his life to fit the circumstances. Often it is advisable to outline treatment procedures as well as the overall rehabilitation program.

The rehabilitation of any cardiac may involve family members, nurses, teachers, social workers, vocational counselors, psychologists, psychiatrists, surgeons, cardiologists, occupational therapists, dietitians, industrial physicians, employers, union leaders, personnel directors, fellow workers, and friends. Although many disciplines and individuals may be employed in the rehabilitation program, the patient's personal physician must remain his guide from the time of initial illness until the goal of rehabilitation, namely the return of the patient to the best life he can lead with what he has left, is achieved.

Summary

1. Rehabilitation of the cardiac is a complex process properly initiated by medical, psychological, social, and vocational evaluation of the patient.

2. The rehabilitation program must be individualized to meet the specific needs of the patient.

3. The single most important step in the rehabilitation of the cardiac is the physician's unhurried discussion with the patient about the nature of his disease, its treatment, prognosis, and how he can best arrange his life to fit the circumstances.

4. The rehabilitation of the cardiac may involve many different people, with diverse skills, but the physician must remain the patient's guide until the patient has returned to the best life he can lead with what he has left.

Revised Regulations for Tuberculous Immigrants

Aliens with tuberculosis who are permitted to immigrate to the United States are now required to go promptly to a hospital for examination and necessary medical care, according to a change in immigration regulations announced by the Immigration and Naturalization Service of the Department of Justice and by the Public Health Service. Hospitalization as an inpatient is not necessary if the responsible physician determines that outpatient care is adequate. Earlier regulations provided for hospitalization "if required," without stating details on enforcement.

Public Law 85-316 of September 11, 1957, contains a provision permitting an immediate family member of an American citizen or of a resident alien to immigrate to this country although afflicted with tuberculosis. Other aliens with this disease are barred from admission.

Before receiving an immigrant visa, the alien must submit a statement from a State, Territorial, or local health officer, or from the director or a physician staff member of a hospital recognized by the Public Health Service as an institution for the treatment of tuberculosis, agreeing to supply any treatment and observation required for proper management of the alien's condition, in conformity with accepted local standards of medical practice.

This statement must also provide that the United States quarantine station at New York will be furnished a clinical evaluation of the alien, including necessary X-ray films, and a report of final disposal of the case. In each instance the statement of agreement regarding these services must specify the name and address of the hospital at which the services will be provided, and must stipulate that the alien will

be given care on an inpatient or outpatient basis when necessary after his arrival at the hospital.

In applying for his immigrant visa the alien must also submit:

- An affidavit from a sponsor or other responsible individual that financial arrangements for the alien's care have been made with the hospital, unless the Dependents Medical Care Act applies.
- Assurance that upon admission into the United States he will go direct to the specified hospital; submit to such examinations, treatment, isolation, and medical regimen as may be required; and remain under the prescribed treatment or observation, whether on an inpatient or outpatient basis, until discharged.
- Assurance that he will comply with the provisions of Sanitary Measures for Travel of Aliens With Tuberculosis. This applies only if the alien's tuberculosis is considered to be in communicable form, in which case he is given a copy of the document.

For purposes of these requirements, the Public Health Service recognizes a hospital as "an institution for the treatment of tuberculosis" if it is listed in Tuberculosis Beds in Hospitals and Sanatoria, Public Health Service Publication No. 518. Copies of this have been sent to State health departments and other local health agencies.

Immigration and Public Health Service officials have expressed the hope that when health departments or qualified private institutions and physicians are called on to provide care for an alien with tuberculosis who is seeking admission to this country, they will carry out the letter of the regulations in order that the spirit of the law may be observed.

Health Needs and Opinions of Older Adults

LENA DICICCO, M.S.P.H., and DORRIAN APPLE, Ph.D.

TO LEARN something about how older people perceive their health needs and how they meet them, an interview survey was conducted among 95 elderly persons living in a low socioeconomic district of Boston, Mass. Although the findings may be characteristic to some extent of the socioeconomic level of the group, they are undoubtedly related in part to the respondents' age. In any event, the group is a sample of potential consumers of public health services. Their behavior, attitudes, and opinions should be of value to public health personnel planning or administering services for such a population.

The study, carried out in 1955, was designed specifically to investigate the following factors and their interrelations: state of health and health care, satisfaction with health, respondents' appraisal of health needs and care, and use of mass media for health information. With a few changes, a number of the questions in the interview schedule were taken from the much more extensive schedule used in the survey in the Kips Bay-Yorkville Health District of New York City (1). Most of the interviewing was done by an interviewer with considerable training and experience on research proj-

ects of the Harvard University department of social relations. The remainder was done by DiCicco.

Characteristics of the Sample

A random sample of 158 persons 65 years of age and over was drawn from a single census tract within the Whittier Street (Roxbury) District of the Boston Health Department. According to the 1950 census, the total population of those ages in the census tract is 377. Median rental in the residential area is \$24 per month; about 35 percent of the housing is dilapidated or has no running water; less than 15 percent of the employed have "white collar" jobs or better; and more than half the population is nonwhite.

The sample yielded 95 interviews. Of the 63 nonrespondents, 26 were men and 37 women; 39 persons (16 men and 23 women) had moved, were deceased, or could not be found; 14 (9 men and 5 women) had working hours that prevented their being interviewed; and 1 man and 9 women refused to be or were incapable of being interviewed because of illness or a language handicap. The interviews averaged an hour in length. Only seven of the respondents showed any negative feelings about being interviewed.

Of the 95 respondents, 25 were between 65 and 69 years of age; 55 were in their seventies; and 15 were 80 or over. Twenty were white men, and 15 were Negro men; 40 were white women, and 20 were Negro women. Forty-four were born in the United States; of the foreign

Miss DiCicco, health educator, and Dr. Apple, sociologist, were members of the staff of the gerontology and chronic disease unit of the Harvard School of Public Health when the survey reported here was undertaken. Miss DiCicco is presently on the staff of the health division of United Community Services of Metropolitan Boston. Dr. Apple is with the Boston University School of Nursing.

born, 18 were born in Canada, 11 in Ireland, 7 in the British West Indies, and the remaining 15 in 13 other countries. The mean length of residence in this area of Boston was 40 years.

Twenty-nine of the respondents were married; 58 were widowed, divorced, or separated; and 8 were single. Besides the 29 married respondents, who were living with their spouses, 30 persons were living alone, 25 were living with relatives, and 11 were living with nonrelatives. Twenty-one reported owning their own homes, and 74 were tenants or lodgers. Fourteen persons had finished high school; 28 had attended high school; and 53 had not completed grammar school. Forty-six were Protestant; 40 were Roman Catholic; and 3 were members of other faiths; the others did not designate a religious affiliation. Eighteen had never worked; 14 were currently employed; and 63 had previously worked.

In summary, the sample included substantial numbers of whites and nonwhites, Roman Catholics and Protestants, native born and foreign born. The preponderance of women, the low educational level, the few still employed, and the small number living with spouses are characteristic of older persons. Their poverty and substandard housing are characteristic of the area in which they live.

The race and sex distributions of the sample were representative of the distributions of all persons aged 65 years and over in the census tract. The sample, however, tended to be older than the census tract population. Half of the 377 persons 65 years old and over in the census tract were in the 65-69 group, but only one-fourth of the sample were in this age category. The difference is probably due to the number of persons in the lower age group who were not interviewed because of their working hours.

State of Health and Health Care

The state of health of the respondent was determined through questions about the number of days spent in bed during the previous year, ailments or symptoms present at the time of the interview, and whether he was under treatment by a physician. Conditions were considered to be under treatment if medication prescribed by a physician was being taken or if the

patient had been seen by a physician within the previous 6 months.

Only two-fifths of the sample reported having been in bed because of illness during the previous year. Thirty-three persons said they had been ill once, and 4 had had 2 illnesses each. These 37 persons reported a total of 696 days in bed.

Forty persons said they had an illness under treatment at the time of the interview; 28 reported an illness not under treatment; and 27 reported no illness.

As shown in table 1, of the 208 ailments reported by 68 individuals, heart and circulatory diseases, diseases of bones and joints, and hearing disorders are the three leading categories. These are chronic diseases for which medical science has little to offer in the way of cure. Practice and opinion of the group surveyed, as brought out in the data that follow, reflect a conviction that aches and pains and physical limitations are a part of old age and a general skepticism that anything can be done about them.

Index of Health

From several questions we constructed a single index of health that would distinguish the more healthy from the less healthy persons. With such an index, we could test whether the more healthy differed from the less healthy with regard to other data that we gathered from our sample.

The index we constructed is known as a Gutt-

Table 1. Ailments and symptoms reported by 68 individuals

Ailment or symptom	Number	Percent
Total.....	208	100.0
Heart and circulatory diseases.....	48	23.1

Study Advisers

Assistance in planning the study was provided by a Harvard School of Public Health Advisory Committee composed of Dr. Robert B. Reed, Dr. Beryl Roberts, Dr. Claire Ryder, and Dr. Leonid Snegireff, and Mrs. Marie F. Gately of the Boston Health Department. Dr. Reed, associate professor of biostatistics at the Harvard School of Public Health, helped in selecting the sample and setting up tables as well as with general advice.

The study was financed through grants from the W. K. Kellogg Foundation and the Proctor & Gamble Fund.

man scale. This method of combining replies to several questions into a single score for each person was developed during World War II by social scientists employed by the Army to study experiences and opinions of soldiers (2, 3). It has been used extensively in sociologic research and has a number of advantages over other methods of combining several items of information into a single score. (Every Guttman scale reported in this paper has a coefficient of reproducibility of more than 0.90.)

For example, suppose we have information about the presence or absence of three traits, A, B, and C, in a sample of people. Suppose that these three traits are all indicators of a single underlying characteristic, such as healthiness, and that trait A occurs most frequently, trait B the next most frequently, and trait C the least frequently. If we find that persons who possess only one of the traits possess A, while those who possess two of them possess A and B, then the items form a Guttman scale. We have in our sample only four types of persons: those who have none of the traits, those who have A only, those who have A and B, and those who have all three. This *stairstep* arrangement means that we can conclude that each type possesses a greater degree of the single characteristic underlying the traits than does the type preceding.

Item A in our index of health was based on replies to the question about number of days in bed. Item B was based on an index of satisfaction with health constructed from replies to

five questions: How would you say your health is now? Do you think your health is better or worse than that of other people your age? Is your health better or worse or about the same as it was 10 years ago? Does it keep you from doing things? Does it keep you from seeing people? Item C was based on responses to the question of whether the person was having any present trouble with his health.

Using this scale, we were able to distinguish four types of persons ranging from the most healthy to the least healthy.

As a test of validity, our state of health scale was cross-tabulated with the interviewer's rating of respondents on Zeman's rating scale of activity (4). Zeman's ratings are: (a) capable of unlimited and unsupervised activity; (b) capable of moderate activity in the neighborhood but perhaps requiring assistance for extended or tiring trips; (c) activities limited, needs supervision and assistance a good part of the time, is practically housebound, needs transportation for trips to doctor or clinic; (d) confined to bed or immediate vicinity; (e) totally blind or so self-limited that self-care is not possible. The correlation was 0.59, which is adequate evidence of the validity of our scale. (This and all other correlations were calculated by the formula for the phi coefficient, with both variables dichotomized as close to the median as possible. For this sample, a phi coefficient of correlation greater than 0.21 is large enough to be statistically significant at the .05 level.)

Health Care

We were interested in finding out whether persons who rated low on the state of health scale reported receiving more or less health care than those who rated high. To answer this question we constructed a Guttman scale of health care received. Item A was based on the question of whether the person has a physician or hospital to which he usually goes. Item B was based on replies to this question: Some people think it's a good idea to see a doctor for a regular checkup ever so often even when they aren't sick, while other people think there's no use seeing a doctor unless you have something wrong; what do you think? Item C was based on whether the person said he had

seen a physician for any purpose in the previous year.

We computed a phi coefficient of correlation between health status and health care using types as defined in the state of health scale and in the health care received scale. The two had a correlation of -0.24 , which means that there is a moderate but significant tendency for people who are healthy to stay away from health care (according to their report of their activities) and for the less healthy to receive more health care.

Characteristics of the Two Groups

We were also interested in what differences there were within the "healthy" and the "unhealthy" groups between those who received much health care and those who received little. By thus holding constant the effect of health, we hoped to find indications of the reasons that some persons received more health care than others.

Within each of the two groups, we investigated the relationship between health care and age, sex, race, marital status, native or foreign birth, education, economic level, and whether the person lived alone or not. Within the healthy group, a clear difference emerged in regard to place of birth, marital status, and economic level. (Our criteria for higher, versus lower, economic level were: respondent owns his own home or he is working or chief wage earner of the household is working.) All persons who were native born, married, and economically better off than their neighbors reported a low level of health care. As we proceed to those possessing any two of these characteristics, to those possessing any one of them, and finally to those who are foreign born, non-married, and of a low economic status, the proportion with a high level of health care steadily increases. The difference is great enough for the chi-square test to reject the null hypothesis at the .01 level.

The same relationship between health care and place of birth, marital status, and economic level tended to appear among the less healthy, though the relationship in this group is not great enough to permit rejection of the null hypothesis.

These data indicate that it is likely that hos-

pitals and physicians do not see a representative cross section of the population of older persons whom we studied. Therefore, health services for older people planned on the basis of knowledge of the needs, wishes, and life circumstances of patients may not be acceptable to those who are not seeking health care.

The apparent relation between the amount of health care and the three characteristics might be interpreted this way: All three characteristics have to do with social affiliation. The foreign born have disrupted their early ties by emigrating. Married people have a social tie which the widowed, divorced, and single do not have. Our measure of economic level is home ownership or employment, both of which are social ties. Since receiving health care provides an opportunity for association with other people, it may be that a desire for contact with other persons and a felt lack of social ties lead the foreign born, the nonmarried, and those with a lower economic status to obtain health care. Further research would be needed to test this interpretation. If it were found to be correct, then this motivation for seeking health care might provide a means to increase the utilization of health services by at least a part of the population of older people.

Satisfaction With Health

We hypothesized that a major variable in our sample's evaluation of their health was the degree of activity which a respondent felt he could sustain. Evidence to confirm this hypothesis was found in three ways.

First, interviewer ratings on Zeman's scale of activity had a correlation of 0.54 with our five-item index of satisfaction with health, previously described. This is a highly significant degree of correlation.

Second, the index of satisfaction with health had a correlation of 0.44 with a Guttman scale of respondent's reported activity. The activity scale was constructed from answers to four questions. These concerned (a) visits (sometimes or often) with relatives or friends, either in the respondent's home or elsewhere; (b) walks or rides (sometimes or often); (c) a trip "to town" in the past 6 months, and (d) church attendance (at least once a week).

Finally, a content analysis of statements made by respondents when they were asked how their health compared with that of others their age disclosed that one theme appeared much more frequently than any other. This was the theme of ability to get around, to get out, to do what one has to do. As one lady put it (age forgotten): "He gives me health and strength to get my work done. My 'tired' makes me fall down at night, but then I'm all right for the morning." And one 74-year-old man: "My health is better than some who are 25 or 30. I carry a big buffing machine up and down stairs all by myself."

On the basis of this evidence, we accept the hypothesis that, for a majority of these people, to be active is to be healthy. We may speculate that being active allows older persons to satisfy their need for independence and thus to live up to society's requirements. In this group, health seems to be important only as it affects an individual's capacity to carry on activities important to him.

These findings raise serious questions about the kind of health education that would be meaningful in getting this group under medical care, let alone preventive care. They often consider themselves well despite ailments so long as they can meet the requirements of everyday living.

Respondents' Appraisal

A person's ideas on what constitutes good health and good medical care are important in how well he maintains his health. A number of questions in the interview supply information on how these older people view their health needs and the care they receive.

Periodic Medical Examinations

Respondents were asked when they had last had a "regular, thorough checkup." Fifty-six reported having undergone such an examination within the previous 2 years, but further questioning revealed that only 19 persons, or one-third, had visited a doctor specifically for a checkup. The remaining 37, or two-thirds, explained that the "checkup" was given them when they went for treatment of a disorder.

Thirty-three persons, more than half of the

56, reported that their physical examination had been performed by a private physician.

As a rough measure of the scope of the examination given, information was sought as to how many of the examinations included a chest X-ray, a blood test of some sort, and a urine test. Only 20 persons had had all three and 10 had had none, as shown in the tabulation below. These findings indicate that the examination given most of these people was not a "thorough checkup," although they do not show anything about the adequacy of the examination with regard to the particular disorder under treatment.

<i>Number of tests</i>	<i>Number tested</i>	<i>Percent tested</i>
3-----	20	35.7
2-----	12	21.4
1-----	14	25.0
0-----	10	17.9
Total-----	56	100.0

All 56 respondents who said they had undergone a physical examination expressed satisfaction with the adequacy of the examination.

These facts point to a general misconception in this group as to what constitutes a "regular, thorough checkup," as this would be defined professionally. By the respondents' standards, any contact with a physician, regardless of how the physician might define the purpose of the visit, was apparently a "thorough checkup." It would be valuable to know whether this group is typical of the general population in its apparent lack of knowledge of diagnostic tools.

To obtain further data on attitudes about the value of preventive health services the sample were asked to agree or disagree with two statements: "I think it is a good idea to have a checkup ever so often even though I'm not sick." "Doctors are good people to keep away from when you're feeling well."

About half of the sample agreed with the first statement, but only one-third of the sample disagreed with the second.

In judging the responses to these questions, the consistency in the respondents' answers is important. About 78 percent of the group originally rejecting the idea of preventive care repeated their views when asked the second question. Of the 50 persons who, in answering the first question, professed belief in the idea of

a checkup even though not sick, only 50 per cent were consistent in their answers to the second question. Even more significant is the small number of persons, only 19, who acted on their belief that a preventive physical examination is a good thing.

Some of the negative comments on the subject of preventive care include: "Why go to a doctor when you can always tell when you're getting sick." "Some older people are always running to doctors because they have nothing better to do, and are making themselves sick." "I don't want to worry till I have to." "If you go, he's got to find something wrong with you; it's his business."

The idea that you know when you are sick made some sense 50 years ago when a large proportion of the prevalent illnesses were infectious and were accompanied by symptoms that the layman could recognize as signs of illness. The idea seems particularly inappropriate, however, for an age group prone to chronic diseases, the onset of which may be slow and inconspicuous. It would be interesting to see to what extent these ideas are shared by younger adults who have grown familiar with the preventive aspects of pediatric care, for instance.

As long as people go on measuring health in terms of their ability to eat and sleep or keep going, they will reject the idea that a physical examination is necessary to determine health status.

Preventive Clinic Facilities

In contrast to a majority of the group's negative feelings about the value of a physical examination, about two-thirds stated that they thought older persons would use a special neighborhood clinic where they could get advice and a checkup free of charge. An opinion on this subject was sought in an effort to gain some inkling as to whether this group would use such a service if one should ever be made available.

This generally favorable reaction deserves close scrutiny. It is easy and costs nothing to say yes to an abstract question like this one concerning use of a nonexistent facility for which there will be no direct consumer cost. Also, this same group held few opinions on medical facilities with which they had not had

direct experience. Since the only clinic in the Boston area like the one described was not known to any of the respondents, it is difficult to regard these assents as anything but superficial. Expressed beliefs and practices of this group as revealed elsewhere in the study do not reflect a "felt need" for preventive medical services, however much we would like to think so.

Physicians

Fifty-three respondents said they had a private physician who usually took care of them. How had they selected him? Thirty-eight of them, about three-fourths, said he had been recommended by relatives or friends. Four had heard of him through a social worker, and 11 by various other means.

Respondents' standards for evaluating a physician were elicited by asking how a person can tell whether he can trust a doctor. As this question was added to the interview schedule after some interviews had been completed, we have replies from only 79 persons. One theme in the replies had to do with the doctor's technical competence: "You can tell by his background," or "His treatment works." Another theme had to do with appreciation of the doctor's personal qualities: "I like the kind of person he is," or "I like the way he does things." Table 2 summarizes the data.

Men and women differed significantly in their responses to this question ($\chi^2=8.3$; $P < .02$). Men emphasized the more practical-sounding "satisfaction with treatment"; with women, the doctor's personality seemed to count most. Also, of 15 persons who said they trusted a physician because he was recommended by others (included in the category labeled "other"), 13 were women.

Only two persons named valid criteria for trusting a physician: one, the doctor's background; the other, his staff position in a hospital. The apparent lack of knowledge in this area is not surprising; knowing how to judge a physician presupposes a sophistication about medical matters not usually acquired except through special education or sustained contact with the medical world.

For the same reason, the patient's ability to evaluate his physician's treatment is to be ques-

Table 2. Reasons given by 79 respondents for satisfaction with specific physician

Reason	Male		Female		Total	
	Number	Percent	Number	Percent	Number	Percent
Technical competence-----	12	52.2	11	19.6	23	29.1
Personal qualities-----	6	26.1	25	44.6	31	39.2
Other-----	5	21.7	20	35.7	25	31.6
Total-----	23	100.0	56	99.9	79	99.9

tioned. As one person put it in stating his disadvantageous position: "If you're a patient, you *have* to trust a doctor."

The patient's need to personalize this dependent relationship with his doctor is captured in one woman's statement: "I *must* like him because the doctor will help me if I have confidence in him and if I trust his judgment."

This need to like the doctor as a person is difficult to fulfill within the framework of an overcrowded clinic where many older persons receive care and where treatment is not necessarily always by the same physician. If rewards in the way of treatment are scanty for this age group, how much more is there need for allowing this doctor-patient relationship to develop within the clinic setting!

In general, attitudes toward doctors were strongly positive. Eighty percent disagreed with the negative stereotype, "Doctors aren't really interested in what happens to you," and 73.6 percent denied that "doctors tend to treat younger people better than older people." Also, there were defending statements such as these: "If some old people don't get good service, it's their own fault because they're so cranky and critical." "They're so overcrowded, they do the best they can with what they have."

Medical Facilities

Respondents were asked to name medical facilities they had actually used among the six major hospitals in the Boston area, the city health department, the visiting nurse association, and nursing homes.

Fifteen persons stated that they had never used a hospital service, but the remaining 80 had had 144 hospital admissions. Opinions about 112, or four-fifths of the 144 admissions,

were frankly favorable. Ten persons had had experience with the visiting nurse association and three with the health department, each of whom expressed a favorable opinion of the facility. Respondents were also asked to give opinions on hospitals whose services they had never used, but most of them hesitated to comment without direct experience.

Knowledge and discrimination about medical care and public health facilities are not widespread. This is not surprising since most people are not interested in services until they need them. When they do, there is no readily accessible body of knowledge which could help them in making a wise choice of facilities; and even if there were, according to the data given here and elsewhere, their choice would probably still be based on recommendations of family and friends.

Perhaps the question of sponsorship of a special preventive clinic might be raised here. The desirability of a health department's undertaking this service should be explored carefully, with at least this observation in mind: Most of the group of older people in this study had never used any of the health department services, according to their statements on the subject. Moreover, the disadvantages of separating preventive and curative aspects of child care, for example, are becoming increasingly apparent. Planning of services for older people might well be done with an eye toward integration with facilities and services already known and used by this age group. Integration of a preventive service with other services is particularly important when the need for such a service is commonly unrecognized. Consideration should be given to any practice, no matter how administratively unorthodox, that would en-

hance the possibility of the services being understood and used.

Mass Media for Education

Since so much effort has been directed toward acquainting the public, chiefly through mass media, with some of the basic facts about tuberculosis, cancer, and diabetes, we asked our sample some questions to test their information about these diseases. More than two-thirds of the sample answered questions on tuberculosis and cancer correctly (table 3). Agreement with the statement that cancer can be cured was often qualified by a *doubting tone* or with an additional "so they say" or "they *say* it can." Perhaps information campaigns are allowing the public to make the correct responses while still clinging to old beliefs.

Only about half of the persons interviewed agreed that people with diabetes can lead a useful life, with 33 unable to give an answer. Although the prevalence of diabetes makes it seem likely that everyone is acquainted with the disease, the sizable number of "I don't know's" might reflect the feeling that one can't really judge what it's like for someone else to have the disease.

Questions were asked as to whether the respondent read articles about health in the newspaper or magazines or listened to health programs on the radio or television. There was no significant difference in information about diseases between those who use such media for health information and those who do not.

Of the 86 persons who can read newspapers, 52, or almost two-thirds, said that they read articles on health. However, very few could name columns that they read regularly. Of

the 88 persons who have a radio or television set, only 34, or approximately two-fifths, said that they listen to programs on health. Common replies were: "I don't know why I don't," and "I'm just not interested."

Sex, race, or satisfaction with health status produced no significant differences in responses to these questions.

The picture is quite clear here that, although many people might feel that the aged ought to be interested in knowing more about health and illness, the people themselves probably wish just the opposite, that is, to escape the infirmities coupled with the aging process.

Summary and Conclusions

An interview survey of 95 persons aged 65 years and over who reside in a low socioeconomic district in Boston, Mass., has produced some observations that may be of value to public health personnel in planning and administering services for a similar population.

The most common perception of health among this group was in terms of activity. Health was important only as it became poor health and interfered with daily activity and maintenance of independence.

Since perception of health is an important determinant of one's beliefs and practices in the areas of medical and preventive care, the implications of this perception are significant. It makes for difficulty in motivating such people to seek medical care for the many ailments that are not severely handicapping. And, as borne out by opinions and practices discovered in this survey, it makes even more difficult attempts to make preventive services meaningful.

Among the study group, there seemed to be

Table 3. Public information about tuberculosis, cancer, and diabetes

Statement	Agreed		Disagreed		No answer		Total	
	Number	Percent	Number	Percent	Number	Percent	Number	Percent
People can have tuberculosis and not know it.....	71	74.7	11	11.6	13	13.7	95	100.0
Cancer, if it is found early, can be cured.....	68	71.6	12	12.6	15	15.8	95	100.0
People with diabetes can lead a useful life.....	55	57.9	8	8.4	32	33.7	95	100.0

little appreciation of the newer diagnostic and therapeutic tools, and objective criteria for selecting and judging the quality of medical care received were almost completely lacking. Selection and evaluation of physicians and facilities were made almost completely on the basis of personal experience and opinion of family and friends.

There was little expressed need for preventive services, and for the most part these people had already-established patterns for using medical facilities, based chiefly on personal contacts.

These findings suggest that preventive services for older people probably should be approached from the point of view of integration with services that they consider well established. The services might be paid for by health departments but administered within hospital outpatient departments or departments of welfare.

The frequently mentioned "look at the whole man" is especially important when that man is part of our aging population. The things that give life meaning for him greatly influence the narrow sphere of activities which can be described as health behavior. Sound public health planning cannot be accomplished in a vacuum.

In some communities, public health responsibility might mean taking the initiative to get community concentration on the problem. In those where the framework for action already exists, responsibility might consist of taking

an objective look at all medical and public health services as they affect the elderly, putting new emphasis on already existing programs, and creating new services within whatever agency seems to offer the best chance of being used by the consumer in question.

Migratory Labor Notes Resumed

On April 1, 1958, the Department of Labor resumed publication of *Migratory Labor Notes*, a bulletin describing public and private activities affecting migrant agricultural workers and their families. Issued by the President's Committee on Migratory Labor, the organ first appeared May 11, 1955, and then, reflecting the small number of State migratory labor committees at that time, appeared only intermittently thereafter, once in November 1955 and again in May 1956. Publication on a more frequent basis was stimulated by the growing number of State migratory labor committees, which now total 17, and by the requests of many State and community organizations.

Whether to use septic tank systems to provide needed sewage disposal facilities is an increasingly critical question facing the ever-expanding suburbs.

The Septic Tank System in Suburbia

JAMES B. COULTER, B.S., M.S.

THE WIDESPREAD use of the septic tank has come as a result of an unprecedented demand for housing in suburban areas. Before attempting an evaluation of the septic tank as a means of sewage disposal, it is well to review the factors promoting its use. Since the septic tank is intimately connected with the house-building industry, the review must consider that industry and the forces governing its activities.

After a long freeze during the war, construction got under way in the late 1940's with a mass movement of people to the suburbs of population centers. It seemed reasonable at that time to believe that this shift in population resulted from the wartime backlog of housing demand, that eventually construction would catch up with demand leaving relatively stable communities with new outer boundaries, and that permanent facilities could then be installed to replace the temporary devices used during the expansion period.

It now appears that this reasoning was in error. The tremendous increase in the birth rate following the war was contrary to all predictions. In 1940, the consensus was that the population of the United States had become relatively stationary and perhaps would even

begin to decline. Even as late as 1946 a population of 153 million was forecast for 1960, and an ultimate peak of 164.5 million was predicted for 1990. The great increases in marriages and births following the war made these predictions appear ridiculous. The present population is more than 171 million, and an estimate of 180 million now seems logical for 1960. In fact, during the past 10 years population increase has consistently exceeded the estimates.

The number of immediate housing starts is more nearly associated with new family formation than with population increase. The formation of new families is sagging at present. One reason may be that people of marriageable age are now being drawn from the low birth rate years of the depression, but the high birth rate after the war should bring a population wave in the marriageable age commencing in the late 1960's. Even now we are watching a wave of children pass through grade school. In a few years they will be in high school, later in college, and then they will marry and become prospective home owners.

Family income is another factor that greatly influences house building and home ownership. In spite of increases in the cost of housing, rising family income has brought home ownership within the reach of a large portion of the Nation. The percentage of owner-occupied dwellings rose from 43.6 percent in 1940 to 55 percent in 1950, and a further increase to 60 percent is predicted for 1960 (1). There is also

Mr. Coulter is senior sanitary engineer, Suburban Sanitation Studies, at the Public Health Service's Robert A. Taft Sanitary Engineering Center in Cincinnati, Ohio.

good reason to believe that a rising family income, coupled with modern financing, will lower the age at which first homes are bought.

Suburban Expansion

Considering these facts, housing starts are expected to continue at the present rate of approximately 1 million a year for the next 4 years. Subsequently, the number of starts should steadily increase to a possible 2 million or more a year in the 1970's.

The location of new housing in relation to the central city is extremely important to any consideration of the septic tank's place in fringe area sanitation. Since 1950, practically all of the population increase has been registered in the 172 standard metropolitan areas, but the largest gains have been made on the fringes of the parent cities. This trend is expected to continue (2). To be realistic, we must conclude that the limits of the parent cities are virtually fixed by a number of factors, including the will of the people. Building sites within the corporate limits served by a sewerage system are already scarce and are priced out of the speculative house-building market. Therefore, the vast majority of new houses will be built in the suburbs at an ever-increasing distance from the parent city.

Because of these circumstances, the highway-building program may have more impact on housing location than any other factor in history. Approximately \$40 billion of the estimated \$100 billion to be spent on modern roads in the next decade will be spent in metropolitan areas. As a result, expressways of limited access will lead from the countryside into the heart of all major cities. Since time and not distance is the major consideration of commuters, the expressways will make land, considerably distant from the city, available and attractive for housing. Clearing rights of way during the construction of the highways will generate more pressure for the suburban movement. One noted economist estimated that from 300,000 to 400,000 houses a year demolished in the highway and urban renewal programs will have to be replaced and relocated. Although the estimate appears high, the demolition of houses is undeniably another factor in forcing people to the suburbs.

With the highways will come restaurants, motels, shopping centers, and other service installations. Industries will also locate along the highways, creating still further pressure for fringe area housing. All of these buildings, requiring sewerage and other community facilities, will intensify sanitation needs.

An appraisal of these facts and trends leads to a sobering conclusion. The expansion of standard metropolitan areas is not a passing phase. Rather, we have seen the start of a trend that may continue into the 1980's.

We are entirely unprepared to provide adequate sanitary facilities of all types in a dispersed community of the proportions visualized. The problem of sewage disposal is already acute. In fact, to dispose of sewage properly in an expanding suburban area from the time the first house is occupied until the area is fully developed is perhaps the most complex problem ever faced by the sanitary engineering profession.

Other disciplines are also concerned, but the basic responsibility for supplying essential sanitary facilities is vested in the sanitary engineer. Unless he seizes the initiative and becomes a strong leader, the situation will continue to deteriorate and confusion will increase.

Uses and Drawbacks of the Septic Tank

The problem of sewerage facilities for the rapidly developing, dispersed urban complex springing up around the population centers has no universally acceptable solution. The usefulness and the limitations of each method must be reviewed according to specific circumstances, and the method that can be financed and that shows the greatest promise as a permanent solution should be selected. There is danger in advocating one solution to the exclusion of all others. Conversely no usable solution should be discarded on the basis of experience arising from abuse or improper use of that solution.

The septic tank system, a term I am using to mean the method of on-lot disposal by soil absorption, can be satisfactory for individual homes in a developing suburban area. However, its use must be governed by a number of stringent conditions to avoid extremely unsatisfactory results. When properly used, the system has these advantages:

1. Sewage treatment is complete; the effluent is disposed of on each lot, and each home owner is responsible for his own system.

2. The method is compatible with both the pattern of construction in the United States and the requirements of health authorities.

3. Sufficient capacity to serve each home in a development is added as the house is built.

In general, the usefulness of the septic tank system decreases as the volume of sewage from the individual establishment to be served increases. This limitation is serious when schools, shopping centers, industries, and other larger installations are contemplated for the same general area as the housing. Even though septic tanks may be satisfactory for the individual houses, their use may thwart the construction of a unified sewerage system capable of serving the larger establishments.

The septic tank should never be used where conditions are improper for successful operation. Although frequently used as a temporary measure, the septic tank is actually a poor interim device. Septic tanks have often been permitted in soil where there was little, if any, chance for successful operation, on the assumption that adequate sewerage service would be provided as soon as the population density reached the point where it was practical. Theoretically the temporary use of septic tanks may appear attractive, but practical considerations work against the plan. Some of these considerations are:

1. Immediate failures create nuisances and public health hazards.

2. Many home owners, fearing the effect on property values, refuse to admit that failures are occurring, and do not support remedial action by a community.

3. Not all systems fail at the same time, and home owners who are not having trouble, or who have recently spent sizable sums to repair their systems, are reluctant to agree to community action.

4. There will always be resistance to bond issues and higher taxes. The expense and inconvenience of tearing up streets and lawns to install a community system stymies action until the need is critical.

5. The expense of installing a collection system in an established neighborhood is several

times the cost of the same system in raw land.

Other methods of interim treatment to protect public health should be devised so that the collection system is installed when the houses are constructed, thus eliminating the inconvenience and double expense.

Conditions for Satisfactory Use

A septic tank can be used satisfactorily under certain conditions. These conditions have been reported in a number of technical publications and described in detail in the *Manual of Septic Tank Practice* (3). If recommendations for sewage systems were based on these conditions, the septic tank system would be rejected where it will not work, and complaints stemming from malfunctioning systems would be tremendously reduced. Almost equally important, a system installed under proper conditions which later fails due to misuse, lack of maintenance, or old age can be corrected at the home owner's expense.

Control by a strong, well-organized health department and a sound ordinance are essential to prevent abuses of this system. A good ordinance defines the soil conditions suitable for septic tanks, requires enough usable area on each lot for two complete disposal fields, empowers the proper authority to establish minimum requirements for both septic tank and disposal field, and requires an approved permit before construction starts, individual design and construction by competent, responsible, authorized parties, and a final inspection of the system before it is covered.

The regulation should set forth the soil prerequisites for use of a septic tank system. A reliable percolation test is time consuming and requires great attention to detail. Some health departments feel that the evaluation of land is not a government function but part of the engineering services to be borne by the developer. For this reason, a number of county departments require that every application for a septic tank permit be accompanied by a log of the subsoil and results of percolation tests performed under the direction of a licensed professional engineer or another equally responsible person.

The regulation should also specify the mini-

mum available area that must be provided on each lot for the disposal field. Generally, this is a better practice than specifying lot size; the shape of the lot, the location of the house and driveways, and undesirable terrain features often make it difficult, even on large lots, to find a suitable location for the absorption field. The areas reserved for the system should be large enough to replace the disposal field completely, if necessary.

At the county level, authority to issue septic tank permits is vested in the health department or the building department, but invariably complaints are handled by the health department. Where dual authority and responsibility exist, cooperation between the two departments is essential so that no permit is issued unless the soil conditions are satisfactory and the system is designed in accordance with the regulation.

Inspection is necessary to see that the system was constructed in accordance with the permit and that good construction practice was used. A builder has sometimes been required to remove tile and rock and rework trenches to remove smeared and sealed surfaces. It is necessary also to check the provisions for storm water runoff, the house sewer for stoppages, the tank inlet for clearance, and the distribution box for level, as well as the capacity and construction details of tank and disposal field. Most counties prefer to have their own man make the inspection. The system should be covered as soon as the inspection is completed to protect it from rain and accidental damage.

Important Factors

Soil is the most important natural factor, and the only uncontrollable one, governing the successful use of the septic tank system. To be useful for subsurface disposal of sewage from a large number of homes, an area must have at least 4 feet of cover between the bottom of the disposal field and rock or other restraining formation; the ground water table must be at least 4 feet below the surface of the ground; and the soil must have an acceptable, sustained percolation rate.

For isolated dwellings it may be possible to shade some of these requirements, but for subdivisions all of them must be met. Unfor-

tunately, more than half of the soil in the United States is unsuitable. Furthermore, unsuitable soil is likely to be found on high ground desirable for house building, while suitable soil is likely to be in the bottom land desirable for agriculture. Because no practical method of improving soil for this purpose has been found, the wise builder has learned to make a preliminary investigation before purchasing a tract of land for housing development.

Design starts with the capacity of the system. As water consumption and modern appliances have increased, the concept of increased tank capacity has been readily accepted. Surprisingly, there is resistance, or at least apathy, to enlarging the absorption area even though it is the absorption field that ultimately disposes of the daily volume of liquid.

The relationship between soil area and life of the system is difficult to convey, but it exists nevertheless. Each year an increment of the available absorption area is exhausted and becomes useless for leaching. When the remaining area no longer absorbs the daily volume of liquid the system fails. A 3-bedroom modern house requires approximately 1,000 square feet of design area in a 60-minute soil. Few existing recommendations of local health departments meet that standard. Location, layout, grade, and details of construction are also essential to good design, and for the most part are adequately covered in present recommendations.

Careful construction is as important as good soil. Good construction cannot improve the soil, but good soil can be ruined by poor construction. Within my experience, most early failures of well-designed systems in good soil can be traced to improper construction. Perhaps the worst offense is working the soil when it is too wet. Surfaces are smeared and effectively sealed before any sewage is applied to the system. Walking or working on the absorption surface will compact and seal it prematurely. Raking the sides and bottom of the trench after the soil is relatively dry, and removing all loose rakings before the gravel is laid in the trench is strongly recommended.

Another common fault is to set the distribution box so that most of the liquid goes to one trench. This practice is especially serious and

always leads to failure on sloping ground where the overloaded trench can be relieved only through surface seepage. Occasionally, the box is set correctly and later disturbed by a truck or other piece of heavy equipment running over it.

Open trenches are seldom protected from rainstorms, and surface water loaded with silt is permitted to run into them. Another fault is to permit roof drainage to run over the ground above the disposal field. Wet weather failures can often be traced to this cause. An assortment of articles including tools, rags, lunches, and gloves have been left in house sewers. A frequent mistake is to set the septic tank backwards. The inlet baffle is sometimes broken off, or only a narrow crack is left for sewage to pass through when the house sewer is pushed too far into the tank. The list of construction deficiencies can run into a full scale treatise, but fortunately, installation techniques have improved tremendously in the past few years and are continuing to improve.

Proper use of the system is essential to long and trouble-free operation. Even with good soil, correct design, and proper construction, the home owner can misuse his system and cause it to fail. Using water wastefully or adding appliances can overload the system. Maintenance is simple but essential for a long period of efficient performance. The tank should be inspected annually and cleaned before sludge reaches the level where it is carried to the disposal field and damages the soil. On a lot of sufficient size with the septic tank located properly, failures due to abuse of the system can be corrected by installing a new disposal field. This is of course expensive, and when the home owner is informed of the dangers of abuse and the expense of installing a new disposal field, he is usually very cooperative about proper maintenance of the system.

Summary

The population of the United States is increasing at a rate far in excess of that predicted as late as 1946. Substantially all of the in-

crease is being absorbed in the fringes of the standard metropolitan areas. The growth and decentralization of metropolitan areas is not a passing phase, but rather a major population trend that will continue for many years. The construction of new housing in undeveloped areas creates a problem of sewage disposal of a complexity and magnitude never before faced by the sanitary engineering profession.

The change in community development from the tightly knit parent city of 20 years ago to the sprawling urban complex of today calls for reorientation of plans, philosophy, and techniques if costly errors are to be avoided. The usefulness and limitations of each method of sewage disposal should be reviewed in the light of specific circumstances, and the method that can be financed and that shows the greatest promise as a permanent solution should be selected.

The septic tank system can be a satisfactory means for disposal of sewage from individual houses in a developing suburban area, but its use is subject to a number of stringent conditions if extremely unsatisfactory results are to be avoided. The septic tank is a poor temporary measure, and it should never be used when conditions prohibit its successful operation. In general, the usefulness of the septic tank system decreases as the size of the individual establishment it is to serve increases.

The essential conditions for the satisfactory use of the septic tank system are effective regulation and control, suitable soil, and proper design, construction, and use. Sufficient area should be provided on each lot for replacing the absorption system in case of failure.

Without additional personnel or funds and without appreciably affecting the amount of time spent on other duties, a county health department has established and is now expanding a home safety program based on daily reporting of accident hazards by its field staff.

Growth of an Accident Prevention Program

THOMAS H. GRAY, M.S.P.H., and GEORGE V. TRUSS

AFTER 2 years of studying and experimenting with integration of home accident prevention activities into the routine duties of the department's field staff, the Jefferson County (Ala.) Department of Health has developed a home safety program that is showing definite signs of progress and merit.

Like many other health departments, the Jefferson County agency for many years has recognized and expressed concern about the problem of accidents. Ever since reliable records have been available in Jefferson County, accidents have appeared among the leading causes of death. Safety has been taught by the public health nurses since the beginning of maternal and child health programs. Accident prevention has been a side result of the general sanitation program, although the activities have not been specifically directed toward that goal. Because of insufficient funds, lack of personnel, and a heavy schedule of other duties, no attempt was made to give special emphasis to accident prevention until 1954.

In 1954 the health department decided to remove accident prevention from the realm of thought and discussion and to develop specific plans for active work in home safety. This decision was made without the prospect of ad-

ditional funds or personnel. In fact, the department was seeking some type of program that could be carried out without much added cost.

Advances in the control of the acute communicable diseases and improvement in maternal and infant mortality rates indicated that greater returns from the field staff's time might be realized if safety instruction were made a part of the home visits. Hospitalization and emergency treatment of patients injured in accidents were increasing an already heavy economic burden of medical care for the community's needy. Discontinuance of the local chapter of the National Safety Council also added impetus to the establishment of a health department accident prevention program. Furthermore, the fact that accidents ranked fifth among the leading causes of death in the county during 1954 definitely pointed to the need for such a program. As shown in table 1, home accidents accounted for more than one-third of all accidental deaths in Jefferson County during the 5-year period 1952-56.

As a first step in creating a plan of action against home accidents, a home accident prevention committee was formed within the health department. The committee was composed of the health officer and the directors of the bureaus of public health nursing, communicable disease, sanitation, vital statistics, and health education. Conferences were subsequently held by the committee with home acci-

Mr. Gray is director of the bureau of health education, and Mr. Truss is director of the bureau of records and vital statistics, Jefferson County Department of Health, Birmingham, Ala.

dent prevention specialists of the Public Health Service to obtain advice and guidance in establishing a local program.

Familiar questions arose in meetings of the home accident prevention committee. Where do most accidents occur? How do they happen? Who gets hurt? What is the extent of the problem? What seasonal hazards should be given emphasis?

Morbidity Surveys

To try to answer these questions and to provide data about the nature and extent of non-fatal home accidents in the county two surveys were made in 1954, one in March and the other in June. In addition to collecting data, the surveys were conducted as a means of stimulating interest in home safety among the staff and to provide discussion material for inservice education. The surveys were made also with the idea that the data might be helpful in establishing a baseline for use in measuring indications of progress made in reducing home accidents.

During the survey months every public health nurse, sanitary inspector, and communicable disease officer carried a supply of mimeographed questionnaires. In each home visited they asked whether an accident which disabled the victim for 1 day or more had occurred in the previous month to any member of the household. For each such accident the questionnaire was completed. In every home visited, the name, age, and sex of all household members were recorded to provide a population basis for the study.

It was not considered practicable to visit homes for the sole purpose of making inquiries

regarding home accidents. Generally, therefore, the survey was restricted to the homes that the field staff visited while carrying out their regular duties.

The surveys provided information regarding the accident experience of nearly 48,000 persons living in 10,294 homes. Since the families interviewed included only those visited by the staff in connection with routine health department activities and therefore were not necessarily a representative sample of the county's population, caution was observed in interpreting the results.

The March survey revealed 103 nonfatal home accidents among 24,191 persons. On an annual basis, this means a rate of 55.4 per 1,000 survey population. The 85 home accidents recorded in the June survey gives an annual rate of 42.5 per 1,000 survey population. Falls (39 percent), cutting or piercing injuries (22 percent), and burns (20 percent) were the three principal causes of the accidents, accounting for four-fifths of the injuries reported in the two surveys. Sixty-eight percent, or 128, of the 188 accidents reported in the surveys were in persons under 15 years of age. Only six accidents occurred to individuals 65 years old or over.

No morbidity surveys have been made in Jefferson County since 1954, but the department's accident prevention committee has been considering conducting one in the near future.

Accident Hazard Reporting

Armed with the information from the survey about the principal causes of accidents and about age and sex differentials, and with a more enlightened staff, the health department began

considering ways to attack the problem of home accidents.

We decided that a daily report on accident hazards observed in each home visited would be the most productive and most practical method of integrating accident prevention into the routine activities of the field personnel. Accident prevention efforts would thus admittedly be limited to that segment of the population visited by the health department personnel for other purposes, but we believed that the procedure would nevertheless serve two important purposes: First, the requirement of a report every day would keep each employee safety conscious and constantly aware of the home accident problem. Second, analysis of the data reported would provide statistical information for evaluation and planning of other measures. Moreover, this type of activity could be carried out without additional staff or travel expense.

A special form for reporting home accident hazards was prepared. On it the public health nurses, the sanitary inspectors, and the communicable disease officers were expected to enter each day the number of hazards observed, the number called to the householder's attention, and the number corrected or eliminated, along with a brief description of the hazard. Also required was the number of persons given in-

struction in home safety. The form, shown below, has been in continuous use since March 1, 1955.

The health department's bureau of vital statistics prepared summaries of the hazards reported during the 10-month period of 1955 and during 1956. Copies of the summaries were distributed to all employees so that they might see and study as a whole the accident problem in the homes visited by the field staff.

The number of home accident hazards observed and the number known to have been eliminated are as follows:

	<i>Observed</i>	<i>Eliminated</i>
1955 (March-December) -----	6, 623	1, 825
1956 -----	9, 874	2, 290
Total -----	16, 497	4, 115

During this period the field staff gave person-to-person home safety instruction to 21,147 individuals. Generally this instruction related to a specific hazard in the home at the time of the visit.

The hazards observed can be classified as:

1. Structural deficiencies potentially dangerous as direct or contributing causes of falls and fire burns. These included defective flues and electric wiring, defective steps, and holes in floor.

2. Poor housekeeping, as revealed by yards

Home Accident Prevention Supplemental Daily Report

Description*	Number of home accident hazards		
	Observed	Called to attention of householder	Eliminated

*List hazards, such as unprotected open grate, improper storage of medicine or matches, unanchored rugs, broken glass in yard, unlighted basement steps, etc.

Number of persons given home accident instruction.....

cluttered with broken glass, nails, and other debris, accumulation of papers and other inflammable materials, and floors littered with objects that might cause falls.

3. Lack of supervision of infants and young children, and of the aged, particularly the physically and mentally handicapped.

4. Unsafe practices of adults, such as smoking in bed, using chairs or boxes instead of stepladder, and starting fires with kerosene.

5. Indifference and neglect on the part of householders in providing a safe environment in and around the home.

The address of the home visited was not indicated on the field report, but a great many of the homes listed as having structural hazards were known to be occupied by persons of low economic status. In view of this situation, the number of structural hazards reported as eliminated was encouraging.

The reports provided strong evidence that parents in many homes failed to supervise the activities of children and to give proper care and attention to infants.

Discussion of the hazards with the householders frequently indicated that they were aware of the deficiencies but that they had neglected to take corrective action. Neglectfulness most often prevailed in homes of the lower income group, who were financially unable to provide proper safeguards. This fact pointed to the need for encouraging householders to improvise with scrap lumber and other available materials such things as fireplace screens and porch and step railings.

The hazards found during 1956 ran the whole gamut of accident-producing situations. The principal hazards, according to the kind of injury likely to result, are listed in the accompanying tabulation, with the total number in each main category and of each type (in parentheses) eliminated.

Hazards were recorded as eliminated if corrections were made during the field worker's visit or if observed to have been corrected on a subsequent routine visit. Except for certain major hazards, visits were not made specifically to determine whether or not recommendations for eliminating hazards were carried out. It is therefore not possible to assess the program in terms of the proportion of hazards actually

Number of Hazards Eliminated

Falls.....	569
Defective steps or porches (260); no handrails or balustrades for porches or steps (21); unanchored throw rugs (16); inadequate light in hall or stairs (10); toys, playthings, other objects on floor or walkways (213); miscellaneous (49).	
Burns.....	313
Unprotected open fireplaces, space heaters (47); inflammable objects too close to heating equipment (13); child playing with matches (38); improper disposition of lighted cigarettes (19); unsafe storage of matches (61); hot liquids in reach of children (54); miscellaneous (81).	
Poisoning.....	179
Improper storage of medicine (104); of poisons and household chemicals (48); of fuel oil (26); miscellaneous (1).	
Electric shock.....	17
Defective wiring, worn cords, improper installation of electric wiring, unsafe use of appliances (17).	
Drowning.....	3
Uncovered wells or cisterns, unprotected fish pool, child playing in tub unattended (3).	
Cuts, lacerations.....	704
Broken glass, tin cans in yard, boards with protruding nails (364); child playing with knives, scissors, other cutting instruments (184); sharp objects in reach of children (41); miscellaneous (115).	
Firearms.....	6
Firearms in reach of children (6).	
Suffocation.....	63
Abandoned refrigerator with latch unremoved (11); infant sleeping with parent (40); too much cover on infant (12).	
Strangulation.....	55
Baby nursing from propped bottle (55).	
Ingestion of foreign body.....	77
Child with pennies, marbles, or other objects in mouth (77).	
Miscellaneous and unclassified.....	304
Total.....	2,290

eliminated. It is reasonable to assume that many more unsafe practices have been corrected and dangerous environmental conditions removed as a result of the safety instruction given than the figures in this paper would indicate.

Neither is it possible to determine the number of injuries prevented and the number of lives saved, but the fact that a substantial number of accident hazards are being removed from Jefferson County homes each month is an indication of the program's value.

Many of the hazards reported as corrected were relatively unimportant and at the worse might have resulted only in minor cuts, lacerations, or injuries of slight severity. However, a number of death-producing hazards, such as abandoned ice boxes, uncovered wells, and improper storage of medicine, poisons, and household chemicals, were also recorded as eliminated.

Program Expansion

The department's accident prevention activities were expanded considerably in 1957. Safety education was accelerated through the use of newspapers, radio, and television. Contacts with various community organizations began to pay dividends as evidenced by an increased interest in home safety and mobilization of efforts to reduce the number of home accidents. The Jefferson County Medical Society, the hospitals in the county, and the health department together formulated plans for an active poison control information center and emergency treatment stations. The fire department and the gas and electric companies agreed to provide inspection services for homes upon the request of the health department.

The accident hazard detection program was extended to meat markets, restaurants, grocery stores, and other food-handling establishments visited by sanitary inspectors. Correction of many unsafe conditions and practices in these places, such as improper use of sterilizers and use of broken ladders in storerooms, were recorded during the first 6 months of 1957. It is also noteworthy that one of the sanitary inspectors was instrumental in having a new fire escape installed at a local maternity hospital.

Perhaps the greatest contribution to the accident prevention movement during 1957 was the adoption of a housing code by the city of Birmingham. The new code provides for the immediate correction of existing hazardous conditions as well as for minimum standards for health and safety in all new construction.

Safety features included in the housing code relate to provision of unobstructed and minimum head room for doorways leading outside, installation of railings on unenclosed structures over 3½ feet from the ground, and provision of guard railings on steps containing five risers or more. The new code also states that windows used for ventilation shall have screens; hallways and stairways shall be adequately lighted; and porches and steps shall be so constructed that they will support the normal load expected.

The Birmingham City Commission named the Jefferson County Health Department as the agency for administering the new code and provided a supplemental appropriation for employing additional personnel to carry out its provisions.

Since the adoption of the code, space has been provided on the accident hazard report form for recording addresses where major or special hazards exist, and more intensive followup of the conditions is planned. Significant hazardous conditions are referred to the bureau of communicable disease control for followup and correction. The responsibility was given these staff members because less time is now required for communicable disease control work.

Inservice Training

Training of staff personnel has been carried on in small groups periodically. It has been designed not only to impart information, but to maintain interest in the program. Safety check sheets have been given to staff members for a safety evaluation of their own homes. Group discussions about hazards found during visits and of the accident hazard summaries prepared by the bureau of vital statistics have taken place.

During the training sessions it has been emphasized that changing attitudes and behavior is even more important than eliminating the hazards. The hazards found in homes merely help to create interest in home accidents and to

Table 2. Home accident fatalities, Jefferson County, Ala., 1925-56

Years	Number of deaths	Rate per 100,000 population
1925-29 ¹	109	27.3
1930-34 ¹	81	18.5
1935-39 ¹	96	21.3
1940-44 ¹	89	18.5
1945-49 ¹	95	18.0
1950-54 ¹	94	16.2
1955	104	17.0
1956	77	12.4

¹ Average for the 5 years.

provide a learning situation. No matter how many hazards are discovered and recorded as eliminated, accidents will continue until individuals accept the need for making their homes hazard-free and until they begin to practice safe ways of doing things.

Preliminary Evaluation

The forms for reporting accident hazards have served the useful purpose of creating an awareness among the staff of the numerous and complex problems associated with home accidents. In addition they have provided an index of the staff's ability to integrate home safety with their routine duties.

Both the number of home accident fatalities and the death rate for home accidents in the county show a decreasing trend over the past years, as revealed in table 2.

This decline is not assumed to be due alone to the activities of the department, for there have been other agencies, organizations, and groups active in promoting home safety. It is believed, however, that during the period March 1955 to December 1956, the staff's contact with 21,147 individuals in the county, the elimination of at least 4,115 hazards, and the effort to encourage practice of safety has contributed to the downward trend in the lives lost through home accidents.

The amount of staff time devoted to home accident prevention activities in a year's period is estimated to be equal to the time of three full-time employees. The department's home accident prevention committee feels, however, that three full-time persons could not possibly give the wide coverage offered by the entire field staff, or receive the same acceptance in the homes.

The department's home accident prevention program is still largely in the developmental stage, but it represents a serious approach to the problem. In the future, accident prevention activities will have an increasingly prominent place in the plans and objectives of the department.

Physician Visits During Summer of 1957

The American people visited their physicians during the months of July, August, and September 1957 at a rate of almost five times a year, according to data gathered through household interviews by the U. S. National Health Survey, Public Health Service.

The Survey report, entitled "Preliminary Report on Volume of Physician Visits, United States, July-September 1957" (see announcement on p. 568), points out that although the interviews occurred at a time of the year when people are least likely to call the doctor, respiratory diseases were probably at above-average levels.

Persons living on farms used physicians' services at a rate of 3.6 visits a year, compared with 4.5 for the rural nonfarm population and 5.1 for the urban population. Nine out of ten of the visits were in the physicians' offices.

Mass Therapy in Attempted Control of Amebiasis in a Mental Institution

M. M. BROOKE, Sc.D., RALPH H. HEEREN, M.D., GRACE M. SAWYER, M.D.,
and DORTHEA STONER, B.S.

DEMONSTRATION of 25 laboratory proved cases of clinical amebiasis in an Iowa State institution for the feeble-minded initiated a cooperative control program. An epidemiological investigation, including examination of stool specimens, revealed that 64 percent of the males and 34.4 percent of the females in two buildings occupied by the more retarded patients were infected with *Entamoeba histolytica*. Experience with clinical cases had shown that the problem was not limited to any one building or area of the institution and, because of the poor personal hygiene of many of the patients, it was not believed that recommended methods of improving sanitation would stop the transmission of intestinal pathogens. It was therefore decided to attempt to control the situation through mass therapy of all the institution's residents.

The Institution

The institution, a hospital and school, is situated on 1,000 acres of land 40 miles north of Des Moines, Iowa. It has dormitories for patients, school buildings, a home for employees, and an administration building with separate hospital wards for men and women and dental, X-ray, and modern medical laboratories. Auxiliary buildings house the power plant, water filtration system, dairy, and farm equipment. Patients reside in sturdily constructed 2- or 3-story brick dormitories, which are well separated on beauti-

fully landscaped grounds. Inside, the buildings are well kept, despite overcrowding at times. Each dormitory has its own kitchen, operated by an employed cook and supervised by the dietitian. Most buildings have a dining room on each floor.

In 1951-53, the period of the study, there were approximately 1,600 feeble-minded and epileptic patients in the institution, ranging in age from 1 month to 80 years. Men and women patients were approximately equal in number. The 262 employees included 22 professional individuals, among them 9 physicians, 6 registered nurses, and a dietitian, and 105 supervisors or attendants in the dormitory buildings. Patients helped in such activities as serving food, washing dishes, feeding bedridden patients, cleaning floors, and changing beds.

Patients in a given dormitory were somewhat comparable mentally and physically. The pop-

Dr. Brooke is chief of the Microbiology Section, Laboratory Branch, Communicable Disease Center, Public Health Service, Atlanta, Ga.; Dr. Heeren is director, division of preventable diseases, Iowa State Department of Health, Des Moines; Dr. Sawyer is superintendent, and Mrs. Stoner is medical technician, Woodward State Hospital and School, Woodward, Iowa. Mrs. Sadie Johnson Geiger, Public Health Service Communicable Disease Center, gave technical assistance, and Miss Helen Bradley, formerly of the Iowa State Health Department, kept careful records during the study.

ulation composition of the eight dormitories was:

Type of patient	Buildings	
	Male patients	Female patients
Laundry, dairy, and garden workers.	Birches	Larches
School children-----	Hemlock	Westwood
Delinquent and low grade..	Oak Hall	Maple Lodge
Low grade-----	Pinehurst	Elm Crest

Although the personal hygiene of patients in Birches and Larches Buildings was almost equal to that of normal individuals, the personal hygiene of those in Pinehurst and Elm Crest Buildings was very poor. Fecal incontinence was common with 67 percent of the males in Pinehurst and 49 percent of the females in Elm Crest. These patients soiled their beds and clothing with urine or feces, or both. Some were not averse to coprophagy. The personal hygiene of the patients in Oak Hall and Maple Lodge was not much better, but the hygiene of those in Hemlock and Westwood compared favorably with that of the patients in Birches and Larches. Larches was recognized as the "best building" in every respect.

A trial of mass therapy was planned in Pinehurst, the building with the known highest prevalence of *E. histolytica*. Oxytetracycline was selected for use in view of the report by Tobie and co-workers (1) of the virtual elimination of *E. histolytica* in a similar institution at Wassaic, N. Y., by mass therapy with this antibiotic. Two preliminary trials of mass therapy in Pinehurst Building, with 6-month followup, failed to confirm Tobie's work. Therefore, in extending mass therapy to the entire institution, it was decided to administer more than 1 drug at 6-month intervals on 2 occasions. Although the primary objective of the investigation was control of amebiasis, an effort was made to obtain information on the comparative effectiveness of the drugs employed.

Realizing that opportunities for reinfection probably varied from building to building, drugs were randomly assigned to the patients in 4 of the 8 buildings. These patients, constituting the principal study group, were examined to determine both the results of control measures and the relative effectiveness of the drugs. In the other four buildings, a single

drug was used to treat all patients in a building, and patients were examined to determine the degree of control obtained by mass therapy.

Drugs

Three standard amebicidal drugs were given, singly or in combination of two of the three (2, 3). These were oxytetracycline, carbarsone, iodochlorhydroxyquin, or oxytetracycline and carbarsone combined. The dosages were in accordance with the recommendations of Dr. Harry Most of New York University, Communicable Disease Center consultant.

The four therapeutic regimens were administered according to the weights of the patients (table 1). Two formulations of oxytetracycline were used. During the first treatment period in Pinehurst, the 250-mg. capsules were found to be too large for many of the younger patients to swallow, and it was sometimes necessary to mix the contents of the capsules with water. Therefore, oral drops of oxytetracycline were provided for the younger patients and others having difficulty in swallowing. The carbarsone and iodochlorhydroxyquin capsules were swallowed without difficulty. All medication was followed by a glass of water or fruit juice and by examination of the mouths of the patients to make certain that the drugs had been swallowed.

During preliminary trials of mass therapy in Pinehurst, one-half of the daily dosage was

Table 1. Dosages of four amebicidal drug regimens

Drug	Weight of patients (pounds)	Dosage
Oxytetracycline..	>70	2 gm. per day for 10 days.
	<70	1 gm. per day for 10 days.
Oxytetracycline and carbarsone-----	>70	2 gm. oxytetracycline per day for 5 days.
	<70	1 gm. carbarsone per day for 10 days.
Carbarsone-----	>70	1 gm. oxytetracycline per day for 5 days.
	<70	0.5 gm. carbarsone per day for 10 days.
Iodochlorhydroxyquin-----	>70	1 gm. per day for 10 days.
	<70	0.5 gm. per day for 10 days.

given in the morning and the other half in the afternoon. During mass therapy of the entire institution, the daily dosages had to be administered at one time, usually in the morning. A record clerk was always present to record the amount of medication received. Although a physician or a registered nurse was also present, supervisors and attendants often administered the drugs since they knew the idiosyncrasies of the patients and were best able to gain their cooperation.

Before instituting mass therapy in a building, the physician in charge checked the medication for each patient and made any necessary changes. Usually, recommended dosages (table 1) were given the older patients and those in good physical condition, but for very young or debilitated patients, dosages were reduced according to body weight.

When more than one drug was given, the physician changed the randomly assigned drug for persons for whom he considered its use contraindicated. At least once a day during the treatment period, the records of each patient were examined and he was seen by the attending physician. If intolerance to the medication was observed, therapy was changed or withdrawn. However, this was done for less than 3 percent of the patients, none of whom had been selected for examination.

Employees were encouraged to participate in the amebiasis control program by taking one of the medications. If they preferred, they could submit three specimens to the hospital laboratory for examination and, if the specimen was found to be positive for *E. histolytica*, they could be treated by their private physicians.

Collecting and Examining Specimens

Identical methods of collecting and examining fecal specimens were used throughout the study. In order to insure correct identification, specimens were collected in the presence of the ward supervisor or attendant and were brought immediately to a technician stationed in the building. The technician knew the building from which the specimens originated but did not know the drug regimen received. One portion of each specimen was preserved in 5

percent formalin and another in PVA fixative (4), and both portions were forwarded to the parasitology laboratories of the Communicable Disease Center, Chamblee, Ga.

The portions of feces preserved in formalin were concentrated by the formalin-ether sedimentation technique (5). Heidenhain iron-hematoxylin-stained films were prepared from the portions of feces preserved in PVA fixative and were examined with 50 \times and 95 \times oil immersion objectives. Unstained and iodine-stained wet mounts prepared from the concentrate sediments and Heidenhain iron-hematoxylin-stained films were examined for a minimum of 15 minutes each.

Preliminary Trials

Because of the results of Tobie's study (1), it was planned to evaluate the effectiveness of mass therapy through observation of the patients in Pinehurst Building during a 12-month post-treatment period. However, since the infection in Pinehurst was returning to a high level at the end of 3 months, the patients were re-treated 6 months after the first medication. During the first course of therapy, the antibiotic was given in 250-mg. capsules; during the second course, in oral drops. On each occasion, all patients, supervisors, and attendants received a 10-day course of the drug, the dosage depending on the weight and general condition of the patient.

During the 6 months following therapy, new admissions to Pinehurst were kept at a minimum. Any persons who had to be placed in the building were started on a 10-day course of medication 3 days before they were admitted. Also, during this period, the physician in charge was asked to withhold amebicidal drugs from all persons except those with active clinical amebiasis.

In order to evaluate the effectiveness of mass therapy, 125 patients were randomly selected for examination prior to therapy and again 1 month, 3 months, and 6 months after therapy was started. At each examination only 1 specimen was collected from each patient.

Of these 125 patients, 101 submitted specimens at each collection period during the 12 months of the two therapeutic trials. Intesti-

nal parasites were found in 93 of 101 patients, as follows:

<i>Entamoeba histolytica</i> -----	64
<i>Entamoeba coli</i> -----	75
<i>Endolimax nana</i> -----	63
<i>Iodamoeba buetschlii</i> -----	26
<i>Dientamoeba fragilis</i> -----	3
<i>Giardia lamblia</i> -----	11
<i>Chilomastix mesnili</i> -----	19
<i>E. histolytica, E. coli, or E. nana</i> ¹ -----	90

¹ Amebic prevalence rate (6).

For possible future comparison with other studies, there are included in the preceding tabulation and in table 3 figures for amebic prevalence (6). In determining this prevalence rate, a person infected with *E. histolytica*, *Entamoeba coli*, or *Endolimax nana* is counted as a single positive individual. Figure 1 shows the individual prevalence rates of these parasites at each examination.

Prior to the first mass therapy with oxytetracycline capsules, 64 percent of the patients in Pinehurst were positive for *E. histolytica*; 1 month after the beginning of therapy, 4 percent were positive; 3 months after, 18 percent; and 6 months after, 33 percent.

The week following the 6-month collection of specimens, the second mass therapy with oxytetracycline (oral drops) was administered. One month later, the prevalence of *E. histolytica* was reduced to 5 percent but, again, by the end of the 6-month post-treatment period, the rate had risen to approximately one-half of the pretreatment prevalence rate, or 19 percent. The graphs for the prevalence rates of *E. coli* and *E. nana* are similar to that for *E. histolytica*. However, by the end of only 3 months after each medication, the prevalence rates for these two amebae had almost regained the pretreatment levels.

Mass therapy with oxytetracycline had a marked effect upon *Iodamoeba buetschlii*, but apparently none on *Chilomastix mesnili* and *Giardia lamblia*. Prior to the first course of therapy, 26 of the 101 patients who submitted specimens were infected with *I. buetschlii*; 1 month and 3 months after treatment with oxytetracycline, 2 infections were found but none was observed at the next 4 examinations (9 months). The infections with *Dientamoeba fragilis* were too few for consideration.

Table 2. Results of mass therapy with oxytetracycline in Pinehurst Building

Organism	Response in known positives		
	Number positive pretreatment ¹	Percent negative post-treatment	
		1 month later	6 months later
<i>Entamoeba histolytica</i> ---	97	94.8	70.1
<i>Entamoeba coli</i> -----	151	63.6	15.9
<i>Endolimax nana</i> -----	130	49.2	26.9

¹ Sum of positives prior to first and second preliminary trials of mass therapy.

Table 2 presents the observed effectiveness of mass therapy in individuals known to be positive for *E. histolytica* prior to two courses of therapy. Of the 97 patients known to be infected, 94.8 percent were "negative" 1 month later, and 70.1 percent were "negative" 6 months later. The effectiveness of therapy on *E. coli* and *E. nana* was significantly poorer, particularly at the end of 6 months.

Mass Therapy

In extending mass therapy to the entire institution, the 4 drug regimens were administered on 2 occasions 6 months apart. The second time, each patient received a different drug regimen from that he had received previously. The preliminary trials in Pinehurst had indicated that the effectiveness of mass therapy in controlling amebiasis might be determined by examining specimens collected 6 months after therapy. Therefore, specimens were examined the week prior to the first therapy, 6 months after the first therapy and just prior to the second therapy, and 6 months after the second therapy. At each examination, a single specimen was collected from as many as possible of the individuals who had been selected for examination.

Table 3 records the intestinal parasites found in the randomly selected patients in the eight dormitory buildings prior to mass therapy throughout the institution. The prevalence rate for *E. histolytica* ranged from 7 percent in Larches to 46 percent in Oak Hall. At the time

of this examination, Pinehurst residents had already received two courses of therapy. The initial rate for this parasite in Pinehurst had been approximately 64 percent (fig. 1).

During the 12 months following the first course of therapy in the entire institution, all new admissions received the combination therapy of oxytetracycline and carbarsone for 3 days preceding admission to a dormitory.

Although control of amebiasis was the primary objective of the study, an attempt was made to obtain information on the relative effectiveness of the four drug regimens. Preliminary surveys had demonstrated that the prevalence of intestinal amebae varied from building to building in almost direct relationship to the general level of personal hygiene of the patients. Therefore, the dormitories were divided into 2 groups of 4 multiple-therapy buildings and 4 single-therapy buildings.

Multiple-Therapy Buildings

Because the general type of patients varied from building to building, the influence of reinfection on drug evaluation was equalized by randomly assigning all 4 therapeutic regimens to the patients in 4 of the 8 buildings. Birches,

Figure 1. Results of two preliminary trials of mass therapy with oxytetracycline in one building of a mental institution. Incidence of *Entamoeba histolytica*, *Entamoeba coli*, and *Endolimax nana* prior to medication and during the 6-month post-treatment period.

Hemlock, Larches, and Westwood dormitories, which housed the higher grade patients, were selected since it was thought that reinfection would be reduced to a minimum in these buildings. Each time mass therapy was given, all

nal parasites were found in 93 of 101 patients, as follows:

<i>Entamoeba histolytica</i>	64
<i>Entamoeba coli</i>	75
<i>Endolimax nana</i>	63
<i>Iodamoeba buetschlii</i>	26
<i>Dientamoeba fragilis</i>	3
<i>Giardia lamblia</i>	11
<i>Chilomastix mesnili</i>	19
<i>E. histolytica</i> , <i>E. coli</i> , or <i>E. nana</i> ¹	90

¹ Amebic prevalence rate (6).

For possible future comparison with other studies, there are included in the preceding tabulation and in table 3 figures for amebic prevalence (6). In determining this prevalence rate, a person infected with *E. histolytica*, *Entamoeba coli*, or *Endolimax nana* is counted as a single positive individual. Figure 1 shows the individual prevalence rates of these parasites at each examination.

Prior to the first mass therapy with oxytetracycline capsules, 64 percent of the patients in Pinehurst were positive for *E. histolytica*; 1 month after the beginning of therapy, 4 percent were positive; 3 months after, 18 percent; and 6 months after, 33 percent.

The week following the 6-month collection of specimens, the second mass therapy with oxytetracycline (oral drops) was administered. One month later, the prevalence of *E. histolytica* was reduced to 5 percent but, again, by the end of the 6-month post-treatment period, the rate had risen to approximately one-half of the pretreatment prevalence rate, or 19 percent. The graphs for the prevalence rates of *E. coli* and *E. nana* are similar to that for *E. histolytica*. However, by the end of only 3 months after each medication, the prevalence rates for these two amebae had almost regained the pretreatment levels.

Mass therapy with oxytetracycline had a marked effect upon *Iodamoeba buetschlii*, but apparently none on *Chilomastix mesnili* and *Giardia lamblia*. Prior to the first course of therapy, 26 of the 101 patients who submitted specimens were infected with *I. buetschlii*; 1 month and 3 months after treatment with oxytetracycline, 2 infections were found but none was observed at the next 4 examinations (9 months). The infections with *Dientamoeba fragilis* were too few for consideration.

Table 2. Results of mass therapy with oxytetracycline in Pinehurst Building

Organism	Response in known positives		
	Number positive pretreatment ¹	Percent negative post-treatment	
		1 month later	6 months later
<i>Entamoeba histolytica</i> ---	97	94.8	70.1
<i>Entamoeba coli</i> -----	151	63.6	15.9
<i>Endolimax nana</i> -----	130	49.2	26.9

¹ Sum of positives prior to first and second preliminary trials of mass therapy.

Table 2 presents the observed effectiveness of mass therapy in individuals known to be positive for *E. histolytica* prior to two courses of therapy. Of the 97 patients known to be infected, 94.8 percent were "negative" 1 month later, and 70.1 percent were "negative" 6 months later. The effectiveness of therapy on *E. coli* and *E. nana* was significantly poorer, particularly at the end of 6 months.

Mass Therapy

In extending mass therapy to the entire institution, the 4 drug regimens were administered on 2 occasions 6 months apart. The second time, each patient received a different drug regimen from that he had received previously. The preliminary trials in Pinehurst had indicated that the effectiveness of mass therapy in controlling amebiasis might be determined by examining specimens collected 6 months after therapy. Therefore, specimens were examined the week prior to the first therapy, 6 months after the first therapy and just prior to the second therapy, and 6 months after the second therapy. At each examination, a single specimen was collected from as many as possible of the individuals who had been selected for examination.

Table 3 records the intestinal parasites found in the randomly selected patients in the eight dormitory buildings prior to mass therapy throughout the institution. The prevalence rate for *E. histolytica* ranged from 7 percent in Larches to 46 percent in Oak Hall. At the time

by earlier examination. These included all floors of Westwood and the upper floors of Hemlock and Birches. No specimens were collected from Larches. Hence, it is not possible to extend the graph in figure 2 to indicate the prevalence rates at the second 6-month post-treatment period.

The relative effectiveness of mass therapy in these buildings is demonstrated in table 4. Since there were no significant differences between the response to the first and second administrations of mass therapy, the results are combined. Therapy was significantly more effective in Larches and in Hemlock than in the other 2 buildings for practically all species except *I. buetschlii*, which was apparently eliminated in all 4 buildings. All known infections of *E. histolytica* in Larches were "negative" 6 months after the first therapy.

In table 5 are recorded the results of the individual drug regimens in reducing known infections regardless of location. In only one instance, oxytetracycline against *D. fragilis*, was one drug observed to be significantly more effective than the others. Mass therapy, regardless of the drugs administered, was more effective against certain species than against

others. For example, therapy was significantly better against *E. histolytica* (62.5 percent "negative"), than against *E. coli* (50.8 percent) and *E. nana* (48.8 percent), while all known infections of *I. buetschlii* were apparently eliminated by therapy. The results of therapy in the individual buildings are based on too small a sample for analysis.

Single Drug Regimens

A single drug regimen was administered to the patients in Maple Lodge, Elm Crest, Oak Hall, and Pinehurst Buildings on each of the two occasions of mass therapy. Figure 3 presents the prevalence rates of *E. histolytica*, *E. coli*, and *E. nana* in approximately 50 randomly selected patients in each building before and 6 months after each course of therapy. At the end of 12 months a significant reduction in the prevalence of *E. histolytica* was observed in Oak Hall and Elm Crest Buildings, with possible elimination of the parasite in Maple Lodge. An increase in prevalence apparently occurred in Pinehurst during the same period.

In Maple Lodge, prior to therapy with the combination of oxytetracycline and carbarsone, the prevalence rate of *E. histolytica* was 24 per-

four drug regimens were employed in each building. For the second course of therapy, each patient received a different drug, according to the following schedule:

First course	Second course
Oxytetracycline.....	Carbarsone
Oxytetracycline.....	Iodochlorhydroxy-
and carbarsone.	quin
Carbarsone.....	Oxytetracycline and
Iodochlorhy-	carbarsone
droxyquin.	Oxytetracycline

To evaluate the control program within each building, approximately 30 individuals on each of the drug regimens were randomly selected for examination, or a total of approximately 120 persons on each regimen. In all, over one-half of the 869 individuals in the four buildings were selected.

Single-Therapy Buildings

In Elm Crest, Maple Lodge, Oak Hall, and Pinehurst Buildings, which housed the lower grade patients, a single drug regimen was administered at each of the two mass therapy periods. The drugs were changed in each building on the second occasion. To appraise the effectiveness of control of amebiasis, 50 individuals in each building, or approximately 200 of the 747 persons in the 4 buildings, were randomly selected to submit specimens during the 3 designated periods.

Results of Mass Therapy

The results of treatment with 4 drug regimens and with 1 drug regimen are given below.

Four Drug Regimens

Oxytetracycline, carbarsone, iodochlorhydroxyquin, and oxytetracycline and carbarsone combined were given to the patients in Larches, Westwood, Hemlock, and Birches Buildings on two occasions. Figure 2 shows the prevalence rates of *E. histolytica*, *E. coli*, and *E. nana* prior to the first course of therapy and 6 months later, based on the examination of 502 and 468 individuals, respectively. Dash lines are used in figures 2 and 3 since the lines do not indicate actual prevalence trends during the 6 months between examinations. From the experience in Pinehurst Building, it is reasonable

Figure 2. Results of mass therapy with four drug regimens in four buildings of a mental institution. Incidence of *Entamoeba histolytica*, *Entamoeba coli*, and *Endolimax nana* prior to medication and 6 months afterward.

to assume that an immediate decided drop in the prevalence of amebiasis after therapy was followed by a rise.

Prior to the first administration of the drugs, the average prevalence rate of *E. histolytica* in the four buildings was 28.8 percent (fig. 2). Six months later it was 14.4 percent. The prevalence of *E. coli* was also reduced significantly, but not the prevalence of *E. nana*. *I. buetschlii* was practically eliminated, being reduced from 5.7 percent to 0.5 percent; *G. lamblia* and *C. mesnili* were reduced slightly; and the rate for *D. fragilis* remained unchanged. Six months after therapy no infections of *E. histolytica* were found in the patients examined from Larches and the lower floors of Hemlock and Birches Buildings.

After the 6-month post-treatment examination, all patients were re-treated with another drug regimen. Six months later, because of pressure of other work, stool specimens were collected only from the problem areas revealed

¹ Sum of positives prior to first and second therapy.

² 6 months following treatment.

practically unchanged 6 months after the second.

In Pinehurst Building, prior to therapy with carbarsone, the prevalence rate of *E. histolytica* was 34 percent; 6 months later, before therapy with the combination of oxytetracycline and carbarsone, it was 41.1 percent. Six months after the second therapy, the prevalence rate was 46.3 percent. Mass therapy with either drug regimen appeared to have little or no effect on the prevalence of *E. nana* and *E. coli*.

Since the patients in the four buildings did not receive the same medication, the relative effectiveness of mass therapy cannot be compared according to the response in known positives as was done in the case of the buildings where identical medication with four drug regimens was given (table 4). Likewise, since the type of patients varied from building to building, it is not practical to compare the effectiveness of the individual drug regimens as was done in the other buildings (table 5).

Treatment of Employees

All save 18 of the 262 employees in the institution received amebicidal drugs during the

mass therapy program. The 105 employees working in the 8 dormitories generally received their medication along with the patients. Most of the 18 untreated individuals were in administrative or professional positions. Two *E. histolytica* positive employees in Elm Crest refused therapy. Prior to the mass therapy program the examination of a single stool specimen each from 128 employees revealed 3.9 percent positives for *E. histolytica*.

Toxicity of Drugs

Since only standard amebicides of known toxicity were used in this study, physicians and nurses were primarily concerned only with those side reactions which might endanger the patients or interfere with proper administration of the medication. Aversion to the oral drops of oxytetracycline was the most troublesome side reaction. Although the younger children liked the sweet, cherry flavor of the oral drops, a number of the older patients, particularly the teen-age girls, vomited immediately after the drug was administered. When the drug was given in capsules, the difficulty ended.

cent. Six months later, just before mass therapy with iodochlorhydroxyquin, it was zero. No *E. histolytica* infections were found 6 months after the second course of therapy but the prevalence rates of *E. coli* and *E. nana* were slightly higher than the reduced rates which were found 6 months after the first course of treatment.

In Oak Hall, prior to therapy with oxytetracycline, the prevalence rate of *E. histolytica* was 46 percent. Six months later, immediately preceding therapy with carbarsone, it was 12 percent, and 6 months after the second course it

was slightly higher. The responses of *E. coli* and *E. nana* were similar, although *E. nana* seemed to be affected more by carbarsone than were the other parasites.

In Elm Crest Building, prior to therapy with iodochlorhydroxyquin, the prevalence rate of *E. histolytica* was 29.8 percent; 6 months later, just before therapy with oxytetracycline, it was 22 percent; and 6 months after the second course of treatment the rate was 16.7 percent. The prevalence of *E. nana* was practically the same at each examination while that of *E. coli* was higher 6 months after the first therapy and

Figure 3. Results of mass therapy with single drug regimens in four separate buildings of a mental institution. Incidence of *Entamoeba histolytica*, *Entamoeba coli*, and *Endolimax nana* prior to medication on two occasions and 6 months afterward.

histolytica than against *E. coli* or *E. nana*. This selective action of amebicides in man, particularly the ease of eliminating infections of *I. buetschlii*, has been observed by others (1, 8).

The fact that no significant differences were observed in the activity of the four regimens against *E. histolytica* does not, of course, mean that none existed. The four drugs were randomly assigned to patients in four buildings since it was realized at the outset that differences in opportunity for reinfection would make it difficult to compare groups of patients receiving different medications. By randomization, reinfection opportunities were made more nearly equal. The results suggest that reinfections occurred frequently in most of the buildings so that even if certain drugs were significantly more effective than others, the differences may have been masked by the time post-treatment examinations were made. If the investigation had been directed specifically toward drug evaluation rather than toward control, more frequent post-treatment examinations would have been made. This would have required additional technical help, which was not available.

Some differences in drug activity are suggested by the results obtained in the buildings on single therapies. For example, oxytetracycline alone or combined with carbarsone appeared somewhat more effective than the other drugs (fig. 3). Although the superiority of this combination was observed in the treatment of acute amebiasis in Korea (3), caution must be exercised in drawing conclusions from results in the single therapy buildings since the patients were not similar in each building, and in some instances the drugs were given at different times of the year.

Although other workers have reported on mass therapy of patients in selected buildings of mental institutions (1, 9, 10), to our knowledge, this investigation constitutes the first attempt to control amebiasis in an entire institution by mass therapy. Although only limited success was obtained, the authors still believe that mass therapy constitutes the only practical approach to control in mental institutions with amebiasis problems.

Theoretically, the administration of a 100

percent effective drug, combined with a thorough cleanup campaign, would solve the problem. Lacking these two, perhaps idealistic, conditions, the administration of less effective drugs at intervals more frequent than 6 months may accomplish the elimination of *E. histolytica* in such relatively confined populations as exist in mental institutions. Berberian and co-workers (9) found that, after mass therapy with bismuth glycolylarsanilate and chloroquine phosphate, weekly administration of the same combined therapy to one part of the initial population reduced the infection rate of *E. histolytica* to 25 percent and daily administration to another group reduced the rate to 10 percent of the pretreatment levels. Although these results are encouraging, the intervals between treatments are too frequent for practical application in most institutions.

Summary

In an institution of approximately 1,600 mentally deficient patients living in 8 separate buildings, examination of single stool specimens from 667 individuals indicated that at least 29 percent harbored *Entamoeba histolytica*. Prevalence rates ranged from 7 to 64 percent from building to building.

Preliminary tests of mass therapy in the building with the highest prevalence of *E. histolytica* showed that single courses of oxytetracycline did not eradicate all infections and that the incidence of infection rose to one-half of the pretreatment level by the end of 6 months.

When mass therapy was extended to the entire institution, each patient was given 1 of 4 drug regimens—carbarsone, iodochlorhydroxyquin, oxytetracycline, and a combination of oxytetracycline and carbarsone—on 2 occasions 6 months apart. On the second occasion, the drug was changed for each person. Results of examinations performed 6 months after each medication indicated that mass therapy was successful in reducing the prevalence of *E. histolytica* in 7 of the 8 buildings but that the species apparently was "eliminated" in only 3 buildings. The effectiveness of therapy appeared to be related to the prevalence rate of *E. histolytica* in each building prior to medication and to the general level of personal hygiene of the patients.

No serious cases of diarrhea, more than four bowel movements a day, developed either during or within a few days after medication. Also, no cases of pruritus were brought to the attention of the physicians and nurses; however, the patients in the institution are relatively insensitive to such conditions or else accept them as a matter of course.

A few minor rashes were observed in patients receiving oxytetracycline and carbarsone combined but the attending physicians questioned any connection between the rashes and the drugs. One serious rash developed in a patient receiving iodochlorhydroxyquin. Dizziness was reported by one individual on carbarsone.

Discussion

In 1951 Tobie and his co-workers (1) reported virtual elimination of *E. histolytica* infections from a building of Wassaic State School, an institution for mental defectives, by treating all patients with oxytetracycline. Therefore, in our study it was surprising to observe the prevalence rate of *E. histolytica* return to relatively high levels after the use of the same antibiotic in two preliminary trials of mass therapy in Pinehurst Building. In both institutions, a similar course of therapy was used and no new patients were admitted to the buildings during the post-treatment periods without first undergoing therapy.

One striking difference between the two studies which may have contributed to the diverse results was the pretreatment prevalence rates of *E. histolytica*. In Pinehurst Building, one stool examination revealed *E. histolytica* infections in 64 percent of the patients, while at Wassaic four stool examinations showed a prevalence rate of 49 percent. Since more examinations of the Pinehurst patients would undoubtedly have increased the percentage of positives, there was a decided difference in the prevalence rates of *E. histolytica* in the two populations. Inability to eradicate all infections apparently allowed a significant reservoir to remain to reinfect patients through poor personal hygiene.

When mass therapy was administered throughout the entire institution on two occa-

sions, at 6-month intervals, the prevalence rates of *E. histolytica* were significantly lower in 7 of the 8 buildings by the end of the year's study. The effectiveness of therapy varied from building to building and appeared to be related to the prevalence of *E. histolytica* and to the general type of patients residing in the buildings. At the post-treatment examinations, *E. histolytica* was no longer found in residents of the three buildings with the lowest pretreatment prevalence rates (Larches, Hemlock, and Maple Lodge). Two of these buildings were occupied by the higher type of patients. Little or no change was noted in Pinehurst Building, which had the highest prevalence of *E. histolytica* and the most retarded patients.

Although stool examinations were not performed until 6 months after the end of mass therapy of the entire institution, from results observed in preliminary trials in Pinehurst, it is probable that a number of *E. histolytica* infections remained in each building after therapy was completed. In view of the patients' poor personal hygiene the treatment failures probably served as sources of infection. In Elm Crest, two infected employees, one of whom was a cook, may have been another source of infection.

In addition to the human reservoirs, reinfection may have occurred from organisms in the environment. In the first trials in Pinehurst the prevalence of *E. coli* returned to a high level after therapy more rapidly than did the prevalence of *E. histolytica* (fig. 1). Since both organisms were at a low level 2 weeks after therapy, the more rapid rise in prevalence of *E. coli* may indicate that cysts of *E. coli* remained viable in the environment for longer periods than did cysts of *E. histolytica*. Laboratory experimentations (7) have shown that cysts of *E. coli* survive desiccation to a much greater degree than do cysts of *E. histolytica*.

In comparing results of the four drug regimens in the four buildings on parallel therapy, the only observed difference in drug activity was against *D. fragilis*. Oxytetracycline was significantly more effective than any of the other medications in reducing the prevalence of this parasite. All of the regimens apparently eliminated the few known infections of *I. buetschlii* and were more effective against *E.*

Neonatal Response to DTP Vaccines

L. S. GOERKE, M.D., M.S.P.H., PAULINE ROBERTS, M.D., M.P.H., and JOHN M. CHAPMAN, M.D., M.P.H.

IMMUNIZATION and vaccination during the first, second, or third month of life has been advocated by health authorities to provide protection during the period of greatest vulnerability to infection (1-4). As infants are susceptible to pertussis from birth, and fatality is highest during the first 6 months of life, delay in pertussis immunization until 3 to 6 months of age fails to prevent most of the deaths from this disease. In addition, the advent of routine poliomyelitis vaccination requires establishing optimum immunization schedules for diseases for which specific prevention is now available. General concern over the ability of the infant to respond during the first month of life to a variety of antigens, singly or in combination, has deterred early immunization procedures. The tendency to delay immunization has also resulted from unwillingness to expose the newborn to local and systemic reactions that may accompany injection.

Antigens that will stimulate maximum protection in the newborn with a minimum of side reactions are diligently sought. The choice of antigen is complicated by the variation in potency of available preparations (5). Our study measures response to combined immunization initiated within the first 2 weeks of life, compares the response to aluminum phosphate and

aluminum hydroxide adsorbed antigens, and observes local and systemic reactions following the use of each of these preparations.

Method of Study

A group of 112 maternity cases in the seventh and eighth month of pregnancy was selected for study from prenatal clinics of the Los Angeles City Health Department. These patients were selected on the basis of their willingness to cooperate, freedom from disease, stabilized marriage, and stable residence pattern.

Patients in the study were delivered at the Los Angeles County General Hospital. At term or at delivery a 10-ml. sample of blood was collected from the mother. Cord blood specimens were also requested. These specimens were followed by 5-ml. specimens of whole blood collected from the infants at intervals of approximately 1 month, 6 months, and 1 year following completion of diphtheria-tetanus toxoid and pertussis vaccine (DTP) inoculations. The Los Angeles City Health Department laboratory obtained agglutination titers and performed antibody titrations.

Pertussis agglutination titers, based upon the ability of the patient's serum to agglutinate a standard number of *Haemophilus pertussis* organisms, were obtained according to standard methods (6), except that the organisms were incubated overnight at 37° C. and not at room temperature. The titer represents the highest serum dilution showing a 2-plus reaction.

Diphtheria antitoxin titration was performed according to a modification of the method of Frobisher (7). The titration was based on the standardization of a diphtheria toxin, the end reaction in the presence of a known amount of

Dr. Chapman is also with the university. He is professor of epidemiology, School of Public Health, and professor of preventive medicine and public health, School of Medicine. Dr. Roberts is district health officer, Los Angeles City Health Department, Southwest District.

No significant differences were observed in the relative effectiveness of the four drug regimens against *E. histolytica*. However, since the study was primarily concerned with control of infections and was not specifically designed for the evaluation of drugs, this result cannot be taken as conclusive.

Conference on Nurse Traineeship Program

A national conference to evaluate the professional nurse traineeship program of the Public Health Service (title II, P. L. 84-911) will be held in Washington August 13-15, 1958. The program provides financial aid to graduate nurses preparing for teaching, supervisory, or administrative positions in nursing. Since its inception in 1956, the program has awarded 1,387 traineeships through 60 schools of nursing and public health. Funds allocated by Congress total \$5 million.

About 80 recognized authorities from the fields of nursing education, medicine, hospital and public health nursing service, hospital administration, education, and public health administration will participate in the conference. They will determine the adequacy of the traineeship program in meeting the need for administrators and teachers of nursing and make recommendations as to possible modifications in the program.

Dr. John Millett, previously on the President's Committee on Administrative Management, the Social Science Research Council, and the National Resources Planning Board, and currently president of Miami University, Oxford, Ohio, will serve as chairman of the conference.

Figure 1. Pertussis agglutination titers, maternal and cord blood

	1:640								
	1:320	1							
	1:160				1		1		
	1:80	1	2	1					
	1:40	6	2	3	1				
	1:20	5	1	6	1				
	1:10	4							
	<1:10	4	1	1					
Umbilical Cord Blood									
	<1:10	1:10	1:20	1:40	1:80	1:160	1:320	1:640	1:1,280

is shown in table 1. Of the 93 mothers with infants in the study, 61 (65.6 percent) had titers of 1:10 or less. Only 5 had titers greater than 1:80. Cord blood specimens were submitted for testing following 42 deliveries. The quantitative distribution of maternal prenatal and the corresponding cord blood pertussis agglutination titers is shown in figure 1. Higher titers were observed in the corresponding maternal specimens. Titers of 1:10 or less were obtained in 10 of the maternal and in 25 of the cord blood specimens.

The agglutination titers at the time of the first postvaccination bleeding (1 month following third DTP injection), according to the antigen used, are shown in table 2. Higher agglutination levels were observed among the 41 infants who received the aluminum phosphate

adsorbed antigen. The median titer among infants receiving the aluminum phosphate antigen was 1:80 as compared with a median titer of 1:10 among 37 infants receiving the aluminum hydroxide adsorbed antigen.

One month postvaccination titers were determined in 30 of the infants for whom the agglutination level of cord blood was observed at birth (fig. 2). Fifteen of these infants received aluminum phosphate and 15 aluminum hydroxide adsorbed antigen. A comparison of specimens tested 1 month after completion of vaccination with the cord blood specimens shows that 11 infants who received aluminum phosphate and 2 who received aluminum hydroxide adsorbed antigen had an increase in the pertussis agglutination titer to 1:80 or greater.

The ability to maintain the agglutination

antitoxin producing a zone of erythema approximately 1 cm. in diameter in the skin of a guinea pig. A dilution of serum that gave the same reaction as the standard antitoxin to the same amount of toxin was recorded as the same amount of antitoxin as the standard. The response to tetanus toxoid was not determined in this study.

As soon as possible following discharge from the hospital, the infants received the first of three intramuscular (lateral gluteal) 0.5-ml. injections of commercially prepared DTP. Aluminum phosphate adsorbed antigens and aluminum hydroxide adsorbed antigens were used in alternate infants. Each 0.5 ml. dose contained the equivalent of 30 billion *H. pertussis* organisms. All of the initial injections were given within the first 14 days after birth except for one set of twins who were not available for immunization until the 19th day. The first injection was given in the home. The second and third doses were scheduled at intervals of 4 weeks. Followup home visits were made by public health nurses or by physicians to obtain case histories, to observe reactions, and to schedule clinic visits for subsequent injections and collection of specimens. One child health conference session was reserved weekly at the health center for the study cases. Every effort was made to adhere as closely as possible to the schedule for inoculations and collection of specimens. If the patient failed to appear at the clinic as scheduled, the injections were given and the blood specimens collected in the home within 10 days.

Classification of local reactions was based upon the degree of erythema and induration at the site of injection. Local reaction was recorded as mild, moderate, or severe according to the following definitions:

Mild: Erythema of less than 3 cm. in diameter and/or induration persisting for not more than 2 days, or small persistent nodule.

Moderate: Erythema of 3 cm. or more in diameter with induration persisting for more than 2 days.

Severe: Induration progressing to necrosis or accompanied by a wide area of erythema.

Systemic reactions were classified as:

Mild: Temperature not more than 100° F., restlessness, drowsiness, or irritability of less than 12 hours.

Moderate: Temperature up to 101° F., symptoms of illness persisting for 12 hours or more.

Severe: Temperature above 101° F., in the presence of symptoms and signs of illness.

Results

From the 112 pregnant women who entered the study, 93 newborn infants were available for followup. Of these, 78 completed the series of inoculations and submitted at least one postvaccination blood specimen. Second specimens were obtained from 72 infants and third specimens from 54. The median age at the time of collection of each of the 3 specimens was 3.2 months, 8.5 months, and 15 months.

Response to Pertussis Vaccine

The distribution of "prevaccination" titers (as reflected by maternal and cord blood specimens) and of postvaccination titers for infants

Table 1. Pertussis agglutination titers

Titer	All mothers	Mothers of infants in study	Cord	Infant postvaccination		
				1 month	6 months	1 year
1:1,280	0	0	0	1	0	1
1:640	0	0	0	5	1	2
1:320	0	0	1	3	9	2
1:160	6	5	0	14	9	8
1:80	6	5	2	11	12	10
1:40	8	7	3	7	4	4
1:20	17	15	12	7	10	7
1:10	22	18	6	5	6	5
<1:10	53	43	19	25	21	15
Total	112	93	42	78	72	54

had a 1:80 titer and two had 1:10 titer or less 1 year later. Of the 23 infants injected with aluminum hydroxide who had titers less than 1:80 one month following vaccination, 5 had titers of 1:80 or more one year later. Observation of the serum agglutination titers 1 month and 1 year after vaccination indicates that once agglutinins are stimulated, the aluminum phosphate adsorbed antigen was the better of the two in maintaining the titer for 1 year.

Response to Diphtheria Toxoid

Closer agreement was observed between maternal and cord blood diphtheria antitoxin levels (fig. 4) than in pertussis agglutinins (fig. 1). In 9 of 42 cases there was no demonstrable diphtheria antitoxin (less than 0.01 units per

ml.) in maternal and cord blood. Both maternal and cord blood revealed 0.01 units per ml. in 7 cases, 0.1 unit in 12 cases, and 1.0 unit in 2 cases.

Among the 30 infants with a cord blood and 1 postinoculation specimen, 18 showed increases in antitoxin level by the first month after completion of the injections, 9 remained the same, and 3 had a lower level than was observed in the cord blood (fig. 5). The results according to antigen used are as follows:

	Phosphate	Hydroxide	Total
Titer increase-----	9	9	18
Titer same-----	4	5	9
Titer decrease-----	2	1	3
Total-----	15	15	30

Figure 3. Pertussis agglutination titers 1 month and 1 year following vaccination, by type of antigen

p=aluminum phosphate
h=aluminum hydroxide

titer is observed by comparing the titer at the third postvaccination bleeding (1 year after completion of vaccination) with the titers on first postvaccination bleeding (fig. 3). Among the 54 infants from whom 1-month and 1-year postvaccination blood specimens were obtained, 28 received the aluminum phosphate and 26 the aluminum hydroxide adsorbed antigen. Among those receiving aluminum phosphate adsorbed antigen 19 had titers of 1:80 or higher 1 month following vaccination. Of these, 15 had titers of 1:80 or more 1 year following vaccination. Among the infants receiving aluminum hydroxide who were successfully followed for 1 year, 3 had titers of 1:80 or more 1 month following vaccination. One of these

Table 2. Pertussis agglutination titers 1 month following vaccination, by type of antigen

Titer ¹	Aluminum phosphate	Aluminum hydroxide
1:1,280-----	1	0
1:640-----	5	0
1:320-----	2	1
1:160-----	12	2
1:80-----	9	2
1:40-----	2	5
1:20-----	2	5
1:10-----	0	5
<1:10-----	8	17
Total-----	41	37

¹ Median for aluminum phosphate is <1:80; aluminum hydroxide is >1:10.

Table 3. Pertussis agglutination and diphtheria antitoxin titration 1 month following completion of DTP inoculations, by type of antigen

Pertussis titration	Diphtheria antitoxin units per ml.									
	Aluminum phosphate					Aluminum hydroxide				
	<0.01	0.01	0.1	1.0	Total	<0.01	0.01	0.1	1.0	Total
1:1,280.....				1	1					0
1:640.....		1	1	3	5					0
1:320.....			8	1	9				1	1
1:160.....		1	6	5	12			2		2
1:80.....			4	5	9		1	1		2
1:40.....		1		1	2		2	2	1	5
1:20.....			1	1	2		2	2	1	5
1:10.....					0		2	2	2	6
<1:10.....		3	5		8		7	8	4	19
Total.....	0	6	25	17	48	0	14	17	9	40

diphtheria protection, the following results are obtained.

	PHOSPHATE		HYDROXIDE	
	Number	Percent	Number	Percent
Failure.....	23	48.0	37	92.5
Success.....	25	52.0	3	7.5
Total.....	48	100.0	40	100.0

Selecting a titer of 1:80 or more for pertussis and at least 0.01 AU/ml. for diphtheria as a criterion for protection, the differences in the percent of successes and failures for the two products are greater.

	PHOSPHATE		HYDROXIDE	
	Number	Percent	Number	Percent
Failure.....	12	25.0	35	87.5
Success.....	36	75.0	5	12.5
Total.....	48	100.0	40	100.0

Differences in the antigens with respect to combined diphtheria and pertussis protection 1 year following the inoculations may be derived from table 4. Requiring agglutination at 1:160 dilution and 0.1 AU/ml. as a criterion, 35.5 percent of the infants receiving the aluminum phosphate and 11 percent of those receiving aluminum hydroxide were protected 1 year after the last inoculation. At the levels of 1:80 agglutination and 0.01 AU/ml., 58 percent of the infants injected with aluminum

phosphate antigen, and 22 percent injected with aluminum hydroxide were protected at 1 year.

Reactions Following Injections
